THE ROMANCE OF SCIENCE.

OUR SECRET FRIENDS AND FOES.

EXPANDED FROM LECTURES DELIVERED BEFORE POPULAR
AUDIENCES IN LONDON, EDINBURGH, AND ELSEWHERE.

BY
PERCY FARADAY FRANKLAND,

PH.D., B.Sc. (LOND.), F.R.S.

ASSOCIATE ROYAL SCHOOL OF MINES;

FELLOW OF THE CHEMICAL SOCIETY AND OF THE INSTITUTE OF CHEMISTRY;
FORMERLY PROFESSOR OF CHEMISTRY IN UNIVERSITY COLLEGE, DUNDEE,
ST. ANDREWS UNIVERSITY; PROFESSOR OF CHEMISTRY IN MASON
UNIVERSITY COLLEGE, BIRMINGHAM;
AUTHOR OF 'MICRO-ORGANISMS IN WATER';
'LIFE OF PASTEUR,' ETC.

FOURTH EDITION—REVISED AND ENLARGED.

PUBLISHED UNDER THE DIRECTION OF THE GENERAL
LITERATURE COMMITTEE.

SOCIETY FOR PROMOTING CHRISTIAN KNOWLEDGE

LONDON: NORTHUMBERLAND AVENUE, W.C

43, QUEEN VICTORIA STREET, E.C.

BRIGHTON: 129, NORTH STREET.

NEW YORK: E. & J. B. YOUNG & CO.

THESE PAGES ARE OFFERED AS A SMALL TRIBUTE TO
THE COMPANION WHOSE SYMPATHY AND INVALUABLE
ASSISTANCE HAVE SO GREATLY ENHANCED THE
ENJOYMENT OF SCIENTIFIC WORK.

PREFACE.

THE low forms of life, commonly known as germs or micro-organisms, are daily attracting more and more public attention, as a knowledge of their remarkable powers for good and evil is becoming more widely diffused, and the great strides which have been made in their careful study is undoubtedly one of the most conspicuous features in the past quarter of a century.

This little book, it is hoped, may be a means of making the general reader more intimately acquainted with this recently discovered world of life, and of affording him a glance at its hidden organization and resources.

PERCY F. FRANKLAND.

*University College, Dundee, St. Andrews University,
November 1892.*

PREFACE TO THE SECOND EDITION.

IN the present edition I have added a chapter on the comparatively novel subject of the action of light on micro-organisms, in which the principal results hitherto obtained in this fascinating branch of bacteriology have been brought together.

With the exception of a few mostly verbal alterations, the text of the first edition remains unchanged.

P. F. F.

*Mason College, Birmingham,
1894.*

PREFACE TO THE THIRD EDITION.

THE horizon of bacteriological investigation grows yearly more extensive, and in the present edition I have introduced a chapter dealing with some of the most recent practical applications of this science in the domains both of medicine and agriculture.

P. F. F.

*Mason College, Birmingham,
December 1896.*

PREFACE TO THE FOURTH EDITION.

THE remarkable progress which has been made in the science of preventive medicine has made it necessary to re-write the chapter which I added to the last edition, and I have included some of the latest results achieved in the study of bacterial poisons such as that of bubonic plague as well as in the study of some other poisons of a non-bacterial origin. Bacteriology in its relation to agriculture now forms a separate section.

OUR SECRET FRIENDS AND FOES.

I.

INTRODUCTION.

IF Nature had provided us with eyes one thousand times as powerful as those with which we are at present obliged to be contented, we should form a very different idea of the living world around us. The living creatures, both plants and animals, with which we are now familiar, would fall into utter insignificance, as regards their number, by the side of the countless millions of diminutive living particles which would then come into view. These minute living particles would be seen to infest all our surroundings—floating in the air we breathe, swimming in the water we drink, and in full possession of every inch of the ground upon which we stand and walk.

But although the unaided eye cannot behold

these wonders, the ingenuity of Man has enabled us, with the assistance of the microscope, to discover this new world with its overwhelming multitudes of living beings. It is to these excessively minute living creatures, or micro-organisms, as we now generally term them, and their beneficent and malignant functions in Nature, that I purpose introducing you.

In the first place, let us look into the size and shape of these tiny living forms, which the highest powers of our modern microscopes allow us to discern at least as clearly, sharply, and distinctly as we are able to observe the ordinary objects which surround us.

The minuteness of these organisms is so excessive that their dimensions baffle description in the ordinary terms of measurement. Thus, without going by any means to the smallest known forms, we find as a common length of such organisms the one-twenty-thousandth of an inch—a figure which obviously conveys no definite impression with it. Perhaps it may help you to realize it better if I tell you that no less than four hundred millions of these organisms could be spread over one square

inch in a single layer. Thus we could have a population one hundred times as great as that of London settled on an area of a single square inch, without any complaint of over-crowding, and giving to each individual organism, not three acres—which Radical politicians used to tell us were necessary for the individual man—but one-four-

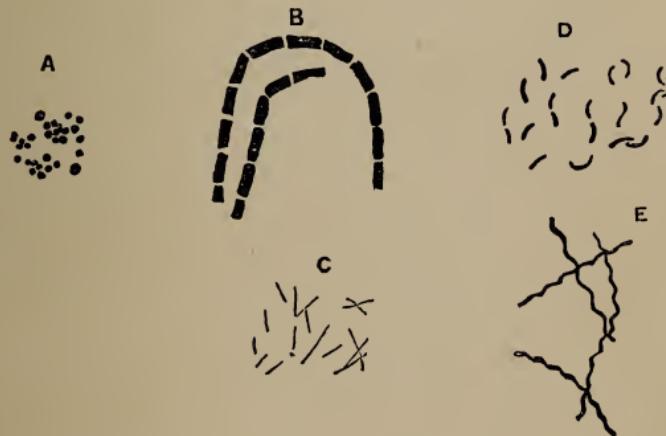

Fig. 1.—Various forms of Micro-organisms.

hundred-millionth of a square inch, which is quite adequate for a citizen in the commonwealth of micro-organisms.

The shape of these “liliputians” is generally very simple. Thus, some are merely more or less spherical granules, to which we give the name of

micrococci (see Fig. I, A); others again, from their rod-like shape, are known as *bacilli* (see Fig. I, B and C); whilst others, having a corkscrew, or spiral form, are known as *spirilla* (see Fig. I, E). Such spirilla sometimes appear in a much shorter form, and then resemble the shape of a “*comma*,” as seen in Fig. I, D. All these various forms are sometimes loosely spoken of as *bacteria*. In addition to these bacterial forms there are two other classes of micro-

Fig. 2.—Yeast-cells.

organisms—the *Saccharomyces* or *Yeasts* (see Fig. 2), and the *Moulds* (see Fig. 3). The yeasts, you see, are comparatively large, oval bodies, whilst the moulds consist of long threads, giving rise to the well-known hairy patches with which we are all so familiar on articles of food, such as jam, bread, and meat, which have been unduly exposed to air and moisture.

Of these variously-shaped micro-organisms the *bacilli* and *spirilla* are motile, or capable of

Fig. 3.—*Penicillium glaucum*.

locomotion, the yeasts and moulds are stationary, whilst the micrococci, which until recently had been classed in this respect with the latter, must now, in consequence of the discovery of some motile forms, rank with the bacilli and spirilla. But by no means all of the varieties of bacilli and spirilla are motile, and it is curious how bacilli, which in almost all other respects closely resemble one another, manifest the most marked difference as regards their powers of locomotion. The movements executed by these motile organisms form one of the most fascinating and entertaining microscopic spectacles which exist. The varied motion of the countless swarms of individuals, following their sinuous paths across the field of the microscope in all directions and in the three dimensions of space, much after the fashion of a cloud of midges playing in the sunshine, produces an irresistible impression upon the observer, that each individual microbe is assisting in and conscientiously performing its part in a highly complex and thoroughly-organized Scotch reel, conducted at express speed.

Interesting and important as it is to observe the

appearance of micro-organisms in a living state, yet this is by no means sufficient for the minute investigation of their form and other characteristics with a view to subsequent identification. The great advances which have been made in our knowledge of micro-organisms within recent years are largely due to the methods which have been devised for accentuating their appearance by means of brilliant colours. Striking colours are employed by both the savage and the civilized man, or rather woman, to render themselves more conspicuous, in the latter case by clothing in coloured garments, whilst by the savage the process of brilliantly colouring the body itself is adopted. Now this is also the process employed by bacteriologists to render micro-organisms conspicuous amongst their surroundings. Their bodies are dyed, and the dyeing is carried out on the same principles as the dyeing of a skein of silk or a hank of wool.

These textile fibres, silk and wool, as is well known to dyers, are most readily coloured by what are called the *Basic Colouring Matters*, to which group belong the brilliant *aniline dyes* like magenta, methyl violet, malachite green, etc.

The great advantage of these dyes consists in the rapidity and intensity with which they colour the materials for which they have an affinity.

It must not be supposed that all materials have an affinity for or can be dyed by these Basic Aniline Colours, and this difference in the behaviour of some substances enables us to distinguish micro-organisms, which readily take up and retain the dye, from their surroundings.

In most cases, however, the staining of micro-organisms is not such a simple matter as this, for the bodies with which they are surrounded have also generally a strong affinity for these basic colours, which results in their becoming also dyed with the colour employed. There is, however, a peculiarity about these micro-organisms which enables us to strongly dye them whilst leaving the surrounding matter colourless or only faintly tinged. The microbes in fact appear to be invested with an envelope which offers great obstacles to the penetration of the colouring matter to their interior. This envelope of the micro-organisms, however, serves to protect them from influences which readily affect bodies not so surrounded, and it

is this circumstance which is taken advantage of in various ways in the dyeing or staining of bacteria.

Thus one of the simplest and most commonly-practised expedients consists in exposing the micro-organisms, and the materials with which they are mixed, to such a temperature that whilst the other materials are so scorched by the heat that they are no longer capable of being dyed, the micro-organisms, wrapped in their protecting blanket, so to speak, suffer practically no injury. On now applying the dye to the scorched specimen, the micro-organisms become strongly and permanently coloured, whilst the surrounding matters remain colourless.

It might possibly be thought a very difficult operation to apply heat so delicately adjusted as to injure these other materials without affecting the micro-organisms, but as a matter of fact with a little experience it can be done with great readiness and facility.

The examination of stained micro-organisms, dyed as I have described, sometimes reveals the presence within the micro-organisms of small

round or oval bodies, which have not taken up the colouring matter. These bodies are the so-called *spores* (see Fig. 4), which, in consequence of their great power of resisting destruction, are of such tremendous importance in the propagation of some micro-organisms, and we shall have to refer to them in greater detail later on. Although sufficiently conspicuous by the fact of their not sharing in the

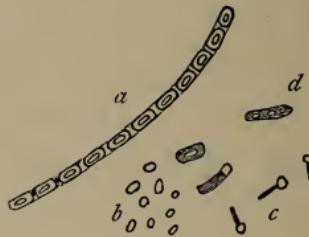

Fig. 4.—Spores : (a) chain of bacilli, each containing an oval spore ; (b) free spores ; (c) bacilli, each with a spore at its extremity ; (d) swollen bacilli containing spores.

gay colours which have been bestowed on the micro-organisms themselves, bacteriological artists are nevertheless fond of painting them also, which can be done by a little modification of the process I have described.

To this end the preparation containing spores is dyed, not with an aqueous solution of one of the basic colouring matters, but with a solution of the

colouring matter in aniline-water, which gives the dye a greater power of penetration. In this manner even the spores become dyed, and *& fortiori* the fully-developed micro-organisms also. The colouring matter, having penetrated into the interior of the spores, is there much more firmly fixed than elsewhere in the preparation, so that if we now submit the latter to a decolourizing process by immersion in dilute nitric acid (1 : 3), the colour will be removed from the spores last.

Having then removed the colour by means of dilute acid from everything excepting the spores we proceed to re-dye the fully-developed micro-organisms by means of another colour in the ordinary way. In this manner a beautiful and most effective microscopic preparation is obtained in which the spores are tinted with one colour and the fully-developed organisms with another.

It is a highly remarkable phenomenon that some micro-organisms offer the same difficulties in the way of being stained as do the spores. This is notably the case with one of the most important of all the micro-organisms with which we are acquainted, viz. the *tubercle bacillus*. The great

value of detecting this bacillus for clinical purposes has led to a number of methods being devised for rendering them apparent through staining. These methods are all based on essentially the same principle as those which I have described for the staining of spores.

The refinements of microscopic technique in connection with micro-organisms have, however, gone even beyond what I have described, for none of the methods of staining already mentioned are successful in displaying certain highly-important structures possessed by some forms, viz. the organs of locomotion by means of which some at least of the motile microbes are able, as we have seen, to propel themselves about in liquid media, often with fabulous rapidity. These organs of locomotion, unlike either the bodies or the spores of micro-organisms, have no affinity for these aniline colours, which we have seen are so useful in exhibiting the latter. In the practice of dyeing textile fibres we are also acquainted with fibres which exhibit the same indifference to these colours ; thus cotton and linen cannot be directly dyed with the Basic Aniline Colours, and in order to dye them with these

colours we have in the first instance to prepare these fibres by impregnating them with what are known as *mordants*. Now this is essentially the principle on which it has been found possible to demonstrate in the most beautiful way the existence of these organs of locomotion, or *Flagella* as they are called (see Fig. 5).

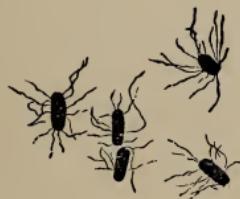

Fig. 5.—Bacilli of Typhoid Fever, showing the Flagella or organs of locomotion. (*After Migu'a.*)

In the accompanying figure a bacillus is seen, from the walls of which most peculiar wavy threads start out in all directions. These are the Flagella, and in some varieties extend, as in this case, in considerable numbers from all parts of the body. In some instances they give rise to a bushy appearance either at one or both ends of the microbe, whilst they are also found single or in pairs (rarely in threes) at either pole. The above drawing is taken from a preparation of the bacillus of typhoid

fever made and photographed by Dr. Migula of Carlsruhe.

It will thus be seen that we are now provided with numerous appliances for carefully studying the form of micro-organisms; indeed, with the best modern microscopes and by careful staining, their outlines are so sharply distinguishable that the most beautiful photographic representations of these minute forms of life are now obtainable.

The process of reproduction amongst the micro-organisms is generally a very simple one, and takes place under favourable conditions with enormous rapidity. The spherical micrococci merely become constricted by a waist, which, becoming more and more fashionable, results in the formation of two distinct bodies from one (see Fig. 6). The

Fig. 6.—Micrococci, showing mode of multiplication.

multiplication in the case of the bacilli is perfectly similar, the division taking place transversely to their length. In many cases, however, the bacilli are capable of another and highly important mode

of multiplication. In the interior of the bacillus there appears a round or oval body, already referred to, having a very bright and shining lustre (see Fig. 4). This bead-like body is known as a *spore*, and plays a most important part in the propagation of many kinds of bacilli ; for just as the seed is much more enduring than the plant from which it is derived, so these spores are capable of resisting many hardships which would be immediately fatal to the parent bacilli from which they have sprung. Thus these spores will endure the severest privations both of hunger and thirst, they are unaffected by cold far greater than that of an Arctic winter, and will sometimes survive a few minutes' exposure to boiling water—in fact, such spores are the hardiest forms of living matter which science has yet revealed.

Having become superficially acquainted with the general appearances of these minute forms of life, we will now endeavour to gain a more intimate knowledge of their habits, and for this purpose we will next consider their distribution.

II.

MICRO-ORGANISMS IN AIR.

THAT the air we breathe is more or less laden with living organisms is a fact which is far from acceptable to most of us, and yet it would require but little persuasion to convince the majority of mankind that air *without* organisms would be undesirable indeed ; for without one micro-organism at least, which is very widely distributed in the air, we should have to forego the numerous and complex uses of alcohol in its various forms.

But there are other micro-organisms in the air besides yeast, and it is the firm conviction that many infectious diseases are propagated by means of air-carried microbes, that renders the investigation of the subject of aërial micro-organisms peculiarly interesting and attractive. Passing over a number of isolated observations by Leeuwenhoek,

Ehrenberg, and Gaultier de Claubry, the systematic examination of the aërial microbia commences with those marvellous discoveries with which the name of Pasteur is so inseparably connected, and with which the latter half of the nineteenth century will for ever be associated. These now classical researches of Pasteur's on the presence of micro-organisms in the atmosphere, were undertaken in connection with the fierce controversy which raged some thirty years ago, on the "*Spontaneous Generation of Life*."

As most of you are doubtless aware, it was contended by the teachers of this doctrine, that the presence of the smallest particle of air was sufficient to determine the generation of low forms of life in certain highly-putrescible substances, such as milk, blood, infusions of meat, and the like. The opponents of this doctrine, marshalled by M. Pasteur, contended, on the other hand, that it was not the air, but certain living germs in the air, which, gaining access to these putrescible materials, gave rise to those growths which make their appearance in them.

"Were this the case," replied his antagonists,

the preachers of spontaneous generation, “these aërial germs would give rise to a fog as opaque and impenetrable as steel.” But Pasteur was not to be shaken in his conviction by dogmatic and baseless assertions of this kind, and he therefore undertook to prove his case by experiments so clinching and unanswerable, that they could leave no shadow of doubt in any unbiassed mind.

The methods by which Pasteur not only revealed the presence of micro-organisms in the atmosphere, but, at the same time, roughly mapped out their distribution, are so striking in their beautiful simplicity, that I must run the risk of being charged with telling again an “oft-told tale,” and refer to them in detail.

The apparatus employed by Pasteur for this purpose consisted of a number of small flasks. Into these flasks, which were about one-quarter of a pint in capacity, was introduced a small quantity of what is known as a cultivating medium, *i.e.* a material in which these lower forms of life are capable of flourishing and multiplying abundantly. The cultivating medium employed in this case was clear broth, which forms an excellent nourishing material for the

greater number of known micro-organisms. The necks of these flasks were then drawn out to a fine aperture (see Fig. 7), and the contents heated to boiling for some time, with the double object of *sterilizing*, or destroying, any living matter in the culture-medium on the one hand, and, on the other,

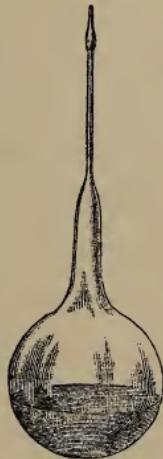

Fig. 7.—Pasteur Flask.

of driving out the air from the flask. The open extremity of the flask was then closed by heating it in the flame of a blow-pipe, whilst steam was still issuing from the mouth.

Pasteur found that the cultivating material in flasks prepared in this way remained sterile, or, as

we should say in homely language, "sweet," for an indefinite period of time.

With a collection of flasks of this kind, Pasteur explored the atmosphere of a number of different places ; for by breaking off the drawn-out extremities of the flasks in any given place, the vacuum inside the flask is immediately filled with the air in question, bringing with it all that it holds in suspension. The broken point is then re-sealed at once before the blow-pipe, and, on preserving the flask at a suitable temperature for a few weeks, the presence of any living organism which has gained access along with the air will manifest itself by its growth in the broth rendering the liquid turbid.

Now Pasteur exposed—

Twenty flasks in the open country of Arbois.

Twenty more on the lower heights of the Jura Mountains.

Twenty more at the Montanvert, close to the Mer de Glace, at a height of upwards of 6000 feet.

These three series of samples were deposited by Pasteur in the bureau of the Academy of Sciences,

in the month of November, 1860. The result, which was awaited with the utmost interest by the numerous *savants* who had taken part in the previous discussions, was as follows :—

Of the twenty flasks opened in Arbois, eight developed living organisms.

Of the twenty flasks opened on the Jura, five became affected.

Whilst of the twenty flasks opened on the Montanvert, only one broke down.

Thus Pasteur succeeded in not only proving the truth of his previous assertions, but demonstrated for the first time the greater relative purity of air at high than at low levels.

Striking as these results are, they can only boast of having roughly mapped out the difference, from a microbial point of view, of the air in these places ; they make no claim to determining the actual number of organisms in a cubic foot or any other given volume of the specified air. Since these first experiments of Pasteur's, numerous endeavours have been made to raise the examination of air for micro-organisms from a *qualitative* to a *quantitative* one. Amongst the earlier workers in this direction

we must mention Miquel and Freudenreich, who devised a method based upon the use of liquid culture media, by means of which they carried out a very large number of experiments, and their results may lay claim to a fair amount of accuracy *inter se*.

Since, however, the masterly researches of Robert Koch have brought so prominently before the world the beautiful methods of cultivating these micro-organisms on a solid instead of on a liquid medium, the problem of approaching the study of the aërial microbia has undergone a fundamental alteration.

The first adaptation of these new methods to the exploration of the air was made by Koch, who exposed dishes containing sterile solid cultivating material, the organisms falling upon which subsequently gave rise by their growth and multiplication to little patches or centres visible to the naked eye. These centres or "colonies," as they have been expressively designated, exhibit often very characteristic appearances, producing very various colours, and growing often in fantastic shapes ; their number can thus be readily counted, and the

members belonging to each colony can be separately studied.

The number found on dishes thus exposed gives no clue to the number of micro-organisms present in a given volume of air, but can only indicate the quantity falling on a given surface in a given length of time. One particularly interesting point was established by the use of this method, for it was found that the colonies consist almost invariably of one family; that they are, in other words, pure cultivations, thus clearly showing that the different varieties of organisms present in the air are separated from each other, and do not occur adhering together.

In conducting experiments on the distribution of organisms in air, I made large use of this method, and employed small circular glass dishes, rather less than one inch in height, and about three inches in diameter, provided with a glass cover fitting loosely, and overlapping like the lid of a pill-box (see Fig. 8). These were filled to a depth of about one-third of an inch with nutrient jelly. This "gelatine-peptone," as it is called, is composed of the finest of French gelatine, to which is added

meat extract, common salt, some peptone, and distilled water. It is deprived of all organic life by being heated for half an hour on three successive days in a steam sterilizer (Fig. 9). In this manner it is surrounded by an atmosphere of steam, and becomes evenly heated throughout the entire volume without the liquid actually boiling, a point of great importance in connection with the preparation of such culture materials. The idea of allowing an interval of time to elapse between the several

Fig. 8.—Culture-dish.

heatings up of the liquid is due to Dr. Tyndall, who, realizing the difficulties presented by the remarkable powers of endurance possessed by the spore (to which we have already referred), thus allowed time for it to develop into a bacillus, in which form it readily succumbs to the action of heat. It was presumed that in two days all the spores originally present in the liquid would have grown out into bacilli, and that the third day's sterilization would finally dispose of these more

readily destructible forms. This has been amply verified by experience, and the science of bacteriology owes an enormous debt of gratitude to Dr.

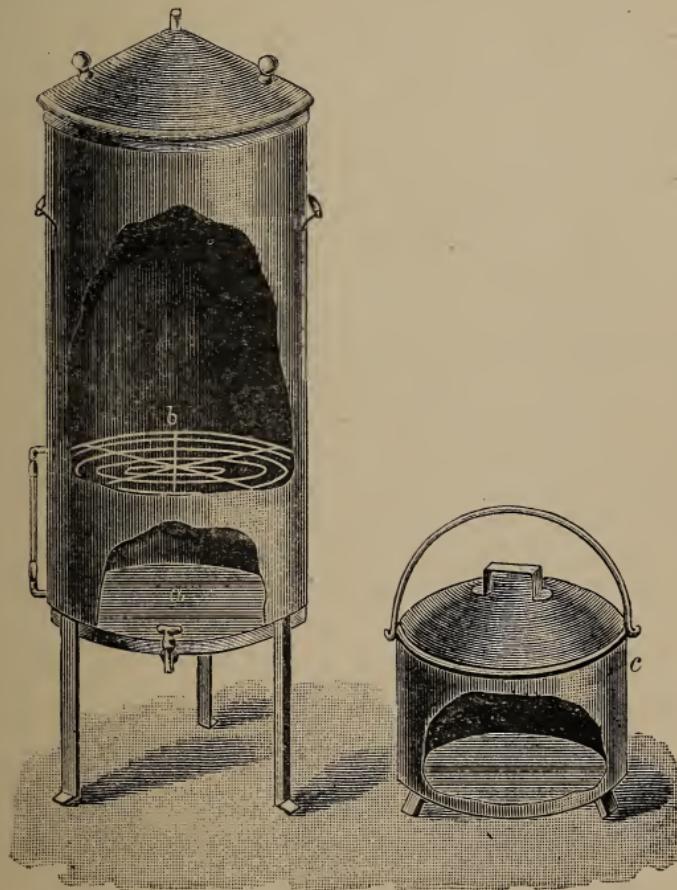

Fig. 9.—Steam Sterilizer: (a) water-chamber in which the steam is generated; (b) wire shelf on which the objects for sterilization are placed; (c) convenient vessel for holding the objects to be sterilized; it is provided with a wire bottom only, so as to admit of the circulation of steam through it.

Tyndall for the introduction of this process, now known as "intermittent sterilization."

In using dishes of gelatine-peptone thus prepared, the lid is removed, and placed with its mouth downwards on a clean surface, and then, after the desired exposure, replaced on the dish.

Some of the first experiments I made were carried out on the roof of the Science Schools, South Kensington Museum, being a distance of sixty to seventy feet above the ground. They were conducted with a view to determining the effect of different climatic conditions on the numbers of micro-organisms in the air, and in each case the number falling per square foot per minute was calculated. It was found that during a high wind the numbers rise considerably; thus in one case during the month of March, the wind rising during a succession of experiments, the numbers found increased from 851 falling on one square foot in one minute at the outset, to 1,302 at the finish.

But on another occasion, when rain had fallen, and the ground and surroundings were thoroughly wet, the numbers found amounted to from 60 to 66

per square foot per minute. Again, during a thick white fog there were present only from 26 to 32. I shall have, however, later on, in connection with the estimation of the aërial microbia in a given *volume* of air, to enter into a more detailed account of the variations occurring over a whole year, and will, therefore, pass on to some investigations made in the interior of buildings by the "dish" method.

We should naturally suppose that when many people are gathered together and much movement is going on, we should find the number of micro-organisms an increasing one. Now, that this is actually the case, is shown by the following experiments made at Burlington House, in the rooms of the Royal Society, during a *Conversazione* very largely attended. At the commencement of the reception, there were 240 microbes falling on a square foot in one minute, but as the rooms became more crowded, the numbers rose to 318, whilst the following morning, when there were only three persons in the room, and everything was covered with dust, the number was reduced to 109.

This point is further strikingly shown by experiments made at the Natural History Museum, South Kensington. The dishes were exposed in the centre of the large entrance hall one Monday morning in May, and again in the afternoon of the same day, when there were considerably more visitors than in the morning. The numbers found were respectively 30 and 293. But these figures sink into utter insignificance when compared with those obtained on a Whit Monday. This being a general holiday there was a very large number of visitors in the building, consequently the amount of disturbance was proportionately great, and the enormous number of 1,755 micro-organisms was found to be falling on a square foot in the course of one minute. The air was also similarly tested during a children's dance. At the beginning, when but a few children had arrived, only 44 were found, but later on, when dancing was going on energetically, this number increased to 400.

Again, in the Richmond Ward (containing eight beds) of the Hospital for Consumption at Brompton, there were found 18 in the morning, but later on

in the afternoon, when more people were moving about, there were as many as 66.

But even these experiments, striking as they appear, are thrown into the shade by comparison with the following figures, obtained under circumstances which would seem to promise as rich a microbial harvest as could possibly be obtained. I was travelling in a third-class railway carriage from Norwich to London, and soon after leaving Norwich I tested the air ; there were at the time four persons in the carriage ; one window was closed, the other open, and the experiment was made near the open window. Under these circumstances 395 organisms were found to be falling on the square foot in one minute. On reaching Cambridge, the carriage was taken possession of by a number of men returning from Newmarket races. The carriage remained quite full (ten persons) to London. About half-way between Cambridge and London I made a second experiment, one window being shut, and the other was only open four inches at the top ; the air was tested near the closed window, with the result that no less than 3,120 organisms were found to be falling on the square foot in one

minute. But this number even was exceeded in an experiment made in a barn in which flail thrashing was going on. The atmosphere was visibly laden with dust, and on testing it with a gelatine dish, I found that upwards of 8,000 organisms were falling on the square foot during one minute.

We must now turn our attention to the estimation of the number of micro-organisms contained in a definite volume of air. I have referred briefly to the liquid culture methods of Miquel and Freudenreich in this direction, but must now pass on to the adaptation of solid media to this purpose.

To rightly appreciate the principle of the "Hesse tube" method, which was the first application of solid media for the volumetric estimation of the aerial microbia, I must go back to some very striking experiments made some years before by Dr. Tyndall, which although more especially directed towards tracing the connection between some of the optical properties of air, and the presence of living organisms, yet revealed the very important fact that in calm air they require a

comparatively short time to subside. As is well known, when a powerful beam of light is passed

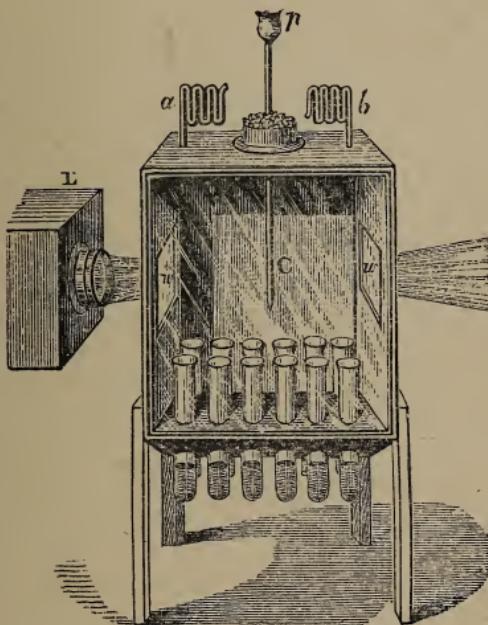

Fig. 10.—Tyndall's Germ-free Chamber. Twelve tubes are shown, containing putrescible materials, like broth, hay-infusion, &c. These liquids have been introduced through the funnel *p*, which can be directed so as to deliver into any one of these tubes. *a* and *b* represent serpentiform tubes, by means of which alone the air inside the chamber is in communication with the outside air. *L* represents a lantern throwing a powerful beam of light, which traverses the chamber through the glass windows, *w w*. The path of this beam within the chamber is invisible, owing to the absence of suspended particles.

through the air of an ordinary room, the path of the beam is rendered visible by the illumination of

a vast multitude of floating particles. Now, Tyn-dall found that if the air in an enclosed chamber be allowed to remain at rest for some time, and a beam of light is then passed through the chamber, its path is no longer visible, the air within the chamber being free from suspended particles capable of reflecting and dispersing the light of the beam. He further showed that this "moteless air," as he called it, was incapable of causing alteration in boiled broth and other cultivating media, or, in short, that the moteless air was sterile or free from micro-organisms.

Now it is this remarkable gravitating property possessed by micro-organisms, thus so conclusively demonstrated, which Hesse has taken advantage of, and which is, in fact, the principle upon which his whole process depends. He makes use of a glass tube about 2 feet 6 inches in length, and $1\frac{1}{2}$ to 2 inches in diameter, coated on its internal surface with, the nutritive gelatine medium. One end of this tube is fitted with a perforated aperture 0.5 inch in diameter, the other extremity being provided with a tightly-fitting india-rubber cork, through which passes a short glass tube, plugged

with cotton wool. The perforated cap is covered with a second non-perforated one, which is tightly wired on so as to be water-tight. The tube is

Fig. 11.—Hesse's Apparatus for estimating the number of Micro-organisms in a given volume of air.

strapped to a small horizontal table supported by an ordinary portable camera stand, the end of the

small tube passing through the cork is connected by flexible tubing with an aspirator, which, so as to render it as portable as possible, consists of two bottles or strong flasks, each of rather more than one quart capacity, arranged as in the figure to form a reversible syphon. A measured volume of water is poured into one of these flasks, and by syphoning this volume into the second, an equal volume of air is made to pass through the tube. The rate of flow is regulated by a screw clamp, and by alternately connecting the end of the tube with the two syphon flasks, any desired volume of air may be drawn through the apparatus. Hesse's experiments show that the rate of aspiration should not exceed one litre in two or three minutes, and that when this precaution is observed, the organisms present in the air are almost wholly deposited in the first two-thirds of the tube, the remaining third being either wholly free or practically so. In the experiments which I conducted with Hesse's method, I fully confirmed the fact of the remarkably complete deposition of the organisms in the front part of the tube, as well as of their being almost uniformly found on the bottom. In commencing

the experiment the outer unperforated india-rubber cap is removed and carefully folded up, so that its inner surface is not exposed to the air, and as soon as the experiment is over it is carefully replaced and wired on. In the course of a few days the number of organisms deposited are readily distinguishable by the colonies visible to the naked eye, or with the aid of a magnifying-glass, to which they give rise. From the number found in a given volume of air the number in any standard volume can be calculated.

I must now pass on to some of the results obtained by this method, and for this purpose I will draw your attention to the following diagram, which embodies observations made on the roof of the Science Schools, South Kensington Museum, over an entire year. You will observe that although the number of micro-organisms in the air frequently undergoes great changes from one day to another, yet the general tendency is for the number to follow the temperature, and that it is during the hottest months of the year—July and August—that the largest number of micro-organisms is present in the air.

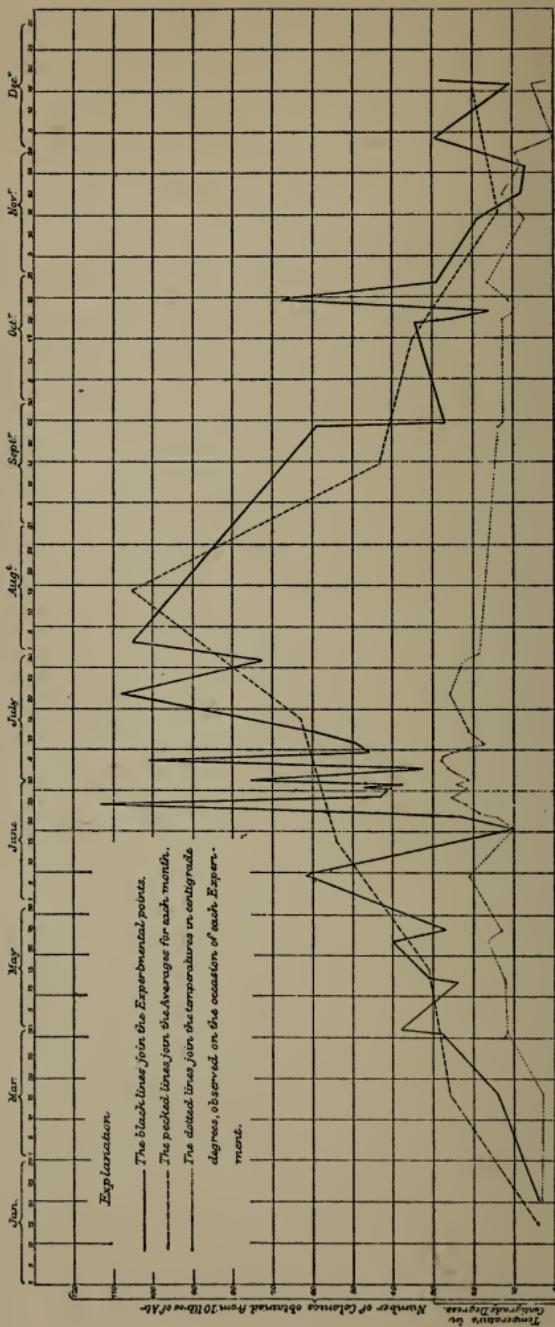

Fig. 12.—Curve showing the monthly variation in the number of aerial Micro-organisms during the year 1886. (*Percy Frankland.*)

I employed this "tube-method" also for the determination of the number of microbes present in air at different altitudes. You will remember that Pasteur already was able roughly to indicate the greater microbial purity of the air high up than on the plain, and the following results fully confirm these early experiments. The spire of Norwich Cathedral is rather more than 300 feet high, but I was only able to get up to a height of 300 feet; even this, however, was sufficient to demonstrate the purity of the air, for in 2 gallons only 7 micro-organisms were found; rather lower down on the cathedral tower, at a height of 180 feet from the ground, 9 were deposited; whilst on the gravel space in front of the cathedral, 18 were found. These experiments were made on one and the same afternoon, so that the results are strictly comparable *inter se*. The dish results were even more striking, for whereas 49 organisms were falling per square foot per minute at the elevation of the spire, at the tower there were 107, and on the ground as many as 354. Experiments made in London at St. Paul's showed the same marked difference. The air at the Golden Gallery con-

tained 11 in 2 gallons; at the Stone Gallery, 34; and in St. Paul's Churchyard, 70; the "dish" experiments yielding respectively 115, 125, and 188. Even the humble elevation of Primrose Hill, Regent's Park, was found to be of importance in this respect, for at the top the tubes yielded 9 in 2 gallons, whilst at the foot there were 24 in the same volume. The dishes confirming these results gave the figures of 12 and 57 respectively.

In striking contrast to the number of micro-organisms found in the various places referred to above, is the number found in the air at sea. Some examinations of sea-air have been made by Dr. Fischer, a surgeon in the German navy, and as he has used substantially the same methods as those described, his results may be fairly regarded as comparative. Dr. Fischer's experiments may be thus summarized:—

- I. Fourteen experiments, with an average of 22 gallons of air, contained no organisms.
- II. Five experiments, with an average of 16 gallons of air, contained 1 organism.
- III. Two experiments, with an average of 22 gallons of air, contained 2 organisms.

IV. Three experiments, with an average of 28 gallons of air, contained 3 organisms.

V. Six experiments, with an average of 12 gallons of air, contained 4·13 organisms.

They may, however, be more instructively classified by taking into consideration the distance from the nearest land at the time of the observations, thus:—

Maximum distance from land in sea-miles, 90; 1 organism to 5 gallons of air.

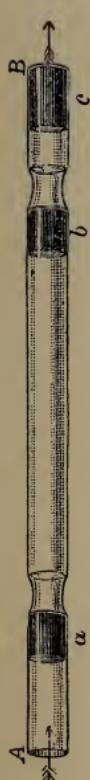

Minimum distance from land in sea-miles, 120; 1 organism to 18 gallons.

Moreover, out of 12 experiments, made at a minimum distance of 120 sea-miles from land, in 11 the air was absolutely germ-free, and in the remaining one only a single organism was found; whilst out of 12 experiments made at a maximum distance of 90 sea-miles from land, in 7 cases organisms were demonstrable, and in only 5 cases not demonstrable. In 3 of these latter 5 cases, however, although the land actually nearest the ship was less than 90 miles, the nearest land in the direction from which the wind was coming was in two cases upwards of 500 miles, and in one case

200 miles. In the other two the land was, in one instance, 60 miles, and in another only 8 miles distant, but in this case the land in question was only a small, slightly-cultivated, and thinly-populated island. This clearly demonstrates, what we should have been led from *& priori* considerations to anticipate, that the principal factor is the distance from land in the direction from which the wind is proceeding. It would further appear that the maximum distance to which, under ordinary circumstances, micro-organisms can be transported across the sea lies between 70 and 120 sea-miles, and that beyond this distance they are almost invariably absent. Of particular interest in these experiments is the very distinct manner in which they show that the micro-organisms which are present in sea-water are not communicated to the air, excepting in the closest proximity to the surface, even when the ocean is much disturbed.

An extended experience with Hesse's method convinced me that it was not without various defects, which besides militating against its convenience also affected its accuracy, and it was with the intention of overcoming some of the difficulties which were

presented by Hesse's process, that I devised the so-called "Flask method," and employed it in carrying out all my later experiments. The air under examination is aspirated through tubes about 5 inches in length, and $\frac{1}{4}$ inch internal diameter. The front end (A) of the tube is open, the other

extremity (B) being slightly narrower. At a distance of 1 inch from the extremity (A) the tube is constricted so as to form a support for the first plug *a*, which is placed just in front of the constriction. At a distance of $2\frac{1}{2}$ inches from the plug *a* the tube is again constricted to form a support for the second plug *b*, whilst resting against the constricted extremity (B) there is a third plug *c* of cotton-wool, which is designed to prevent the introduction of micro-organisms at this extremity of the tube.

Plug *a* is invariably made more pervious than *b*, so that any organisms which may be carried by the current of air

Fig. 13.—Glass tube containing sterile plugs through which the air is aspirated. (*Percy Frankland.*) (a, b) glass-wool plugs for collection of aerial micro-organisms; (c) cotton-wool plug.

through *a* shall find a greater resistance in *b*, and thus, if *b* is found to be altogether free from organisms, it clearly shows that they must have all been arrested by *a*. In order to procure this relationship between the plugs *a* and *b*, the former is constructed of a small quantity either of ordinary glass-wool, or of glass-wool which has been previously coated with cane-sugar, by soaking it in a saturated solution of the latter and then drying. The plug *b*, on the other hand, is constructed of fine sugar or glass-powder (passed through a sieve of forty meshes to the linear inch), supported in front and behind by a layer of glass-wool, either plain, or coated with sugar as above. Each of these plugs is about the size of a pea. Such tubes, ready packed with their plugs, are placed in a tin box, and the lid closed and placed in an oven and exposed to a temperature of 130° C. for three hours ; they can then be kept for any length of time, and easily transported, without fear of contamination, to the place where the experiment is to be performed. When required, the sterilized tube, prepared as above, is carefully taken from the tin box, and is only handled by its ex-

tremity (B). The latter is now attached by means of a piece of stout india-rubber tubing to a piece of lead tubing about ten feet in length, which is clamped at this end (B) to a retort-stand or other convenient vertical support, whilst the other extremity of the lead tube is attached to a T-piece, by which it is connected, on the one hand, with an

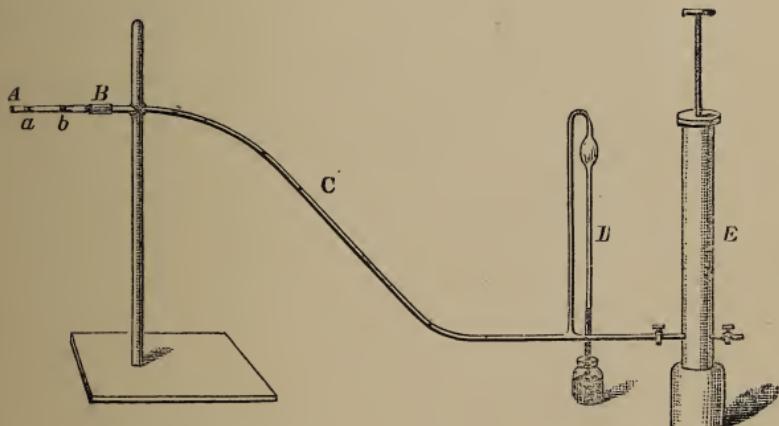

Fig. 14.—Method of aspirating the air through glass tube. (*Percy Frankland.*) (A, B) glass tube; (a, b) glass-wool plugs in ditto; (C) metal tube connecting glass tube with air-pump; (D) pressure gauge; (E) air-pump.

exhausting syringe, and on the other with a mercury pressure gauge, both syringe and gauge being mounted on a rigid support placed upon the ground.

By bending the lead tubing, the experimental tube (A B) is brought into a horizontal position,

and in out-of-door experiments the open extremity (A) is turned away at an angle from the wind. A control-tube is attached by means of wire to the vertical support, so as to rest in a precisely similar position to the experimental tube. The long piece of lead tubing enables the operator to aspirate the air by means of the hand-pump without his movements disturbing the air in the vicinity of the experimental tube, whilst by means of a mirror placed obliquely on the ground, he is able to watch the rise and fall of the mercury in the pressure-tube. After each upward stroke of the pump, the operator waits until the pressure is equalized before making the down-stroke, and by observing this precaution each stroke of the pump corresponds to the passage through the experimental tube of a definite volume of air, which is determined once and for all by means of a gas-meter. Thus, the number of strokes measures the volume of air aspirated, whilst the number of strokes performed per minute indicates the degree of perviousness which the plugs possess. The volume of air aspirated is varied, of course, according to the number of microbes supposed to be present, but with ordinary London air 60 strokes

of the pump, or about four gallons, were found to be convenient. When the desired volume of air has been aspirated through the tube or tubes, the

Fig. 15.—Flasks containing a film of gelatine, upon which the aërial micro-organisms are growing. (*Percy Frankland.*)

latter are at once replaced in the sterile tin box. Flasks, similar to those in the diagram, containing sterile gelatine-peptone which has been rendered

fluid by being slightly heated, are employed for the subsequent development of the microbes caught on the plugs, in the following manner. The tube for examination is carefully removed from the box, and a scratch made with a file intermediate between the plugs *a* and *b*, and the tube broken across. The second half, containing plugs *b* and *c*, is carefully laid aside on a sterile support, whilst the first half is held between the thumb and first finger at the constriction, and the broken edge passed two or three times through a Bunsen flame, care being taken that the heat does not reach the plug. The cotton-wool stopper of one of the flasks is now withdrawn, and the extremity (A) of the tube is held vertically over the open flask, whilst the plug is carefully pushed down by means of a strong piece of sterilized copper wire, introduced from behind through the broken end of the tube. The plug *c* at the extremity (B) is then transferred to a second, and the plug of the control-tube to a third flask.

The gelatine in each flask is then rotated, which, whilst rapidly and completely disintegrating the plug, does not cause the gelatine to froth. This

takes place in a few minutes, and the flask is then held almost horizontally under a stream of water, and by uniformly rotating it an almost perfectly even film of gelatine is spread over its inner surface. After being kept at a suitable temperature the colonies begin to make their appearance. They are easily counted by dividing the flask with ink into segments, and holding them up against the light. The diagram illustrates the appearance of these flasks after the colonies have made their appearance.

By this "Flask method" the microbial contents of a comparatively large volume of air can be collected in a very short space of time, for whilst the aspiration of two gallons of air through Hesse's apparatus takes about three-quarters of an hour, by this method about ten gallons can be drawn through the tube in the same time, whilst by numerous comparative experiments it has been found to yield results under certain conditions greatly superior in accuracy to those obtained by the "tube-process."

Before leaving the subject of air it will be interesting to gain some idea of the appearances which

some of these microbes give rise to when examined under the microscope, and when cultivated in different media. One of these micro-organisms, a bacillus (see Fig. 16 *d*) not more than one-twenty-thousandth of an inch in length, can, by combining the efforts of countless myriads of individuals, produce a most magnificent display of colour when grown on various cultivating media. The intensely blood-red appearance which it presents, has in the past doubtless been the cause of phenomena which at the time were regarded as being elaborated by a miraculous agency, for this *bacillus prodigiosus*, as it is called, finds a suitable soil for its growth and multiplication on bread and other farinaceous articles of food ; thus it has not unfrequently taken up its abode on the sacred wafer, and by there producing this marvellous colour has given rise to the appearance known as the "bleeding host," causing superstitious terror and alarm amongst the ignorant. Fig. 16 *a* represents its appearance as a single colony growing on the surface of the gelatine, magnified about one hundred times under the microscope ; *b* is a smaller colony growing in the depth of the gelatine. Its edge is very irregular, and its

contents are finely granular. After it has been growing for a short time on the gelatine it causes the latter to liquefy. This property of liquefying

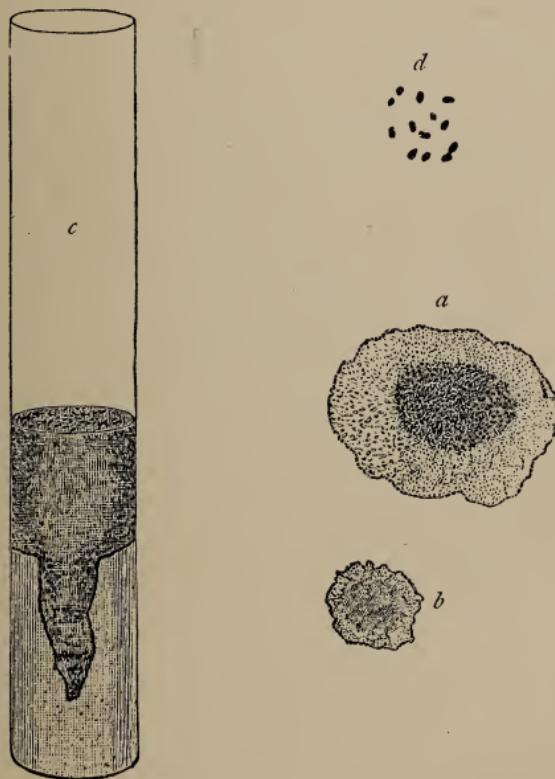

Fig. 16.—*Bacillus prodigiosus*: (a) colony growing on the surface of the gelatine; (b) colony growing in the depth of the gelatine; (c) a gelatine-tube cultivation; (d) individual bacilli magnified about 1000 times. (After Grace C. Frankland.)

the gelatine is due to the peptonizing action of the growth on this material, and is possessed by some

varieties of micro-organisms, but not by others. In Fig. *c* you see what effect it produces when growing in a glass tube partially filled with gelatine. It grows very rapidly indeed, and liquefies the gelatine in the form of a conical sack, which soon extends across the tube at the top, and, gradually passing downwards, involves its whole contents.

But perhaps one of the most common of the aërial microbes is the *Bacillus subtilis*, or the well-known Hay-bacillus, so called because it can be readily procured from hay-infusions. It differs entirely from the *b. prodigiosus*, as will be seen by referring to the next figure. The colonies are some of the most beautiful and characteristic which are known. *a* represents a colony also magnified about one hundred times, growing in the depth of the gelatine ; its contour is irregular, with short, spinose extensions in parts of the circumference, and the interior of each centre has a wavy structure, as if composed of coiled threads. But still more curious are the colonies of the type *b*, composed of parallel bands of fine threads, arranged in a most fantastic pattern ; in the Fig. *c* the two types of colonies are united, whip-like extensions are seen ramifying out

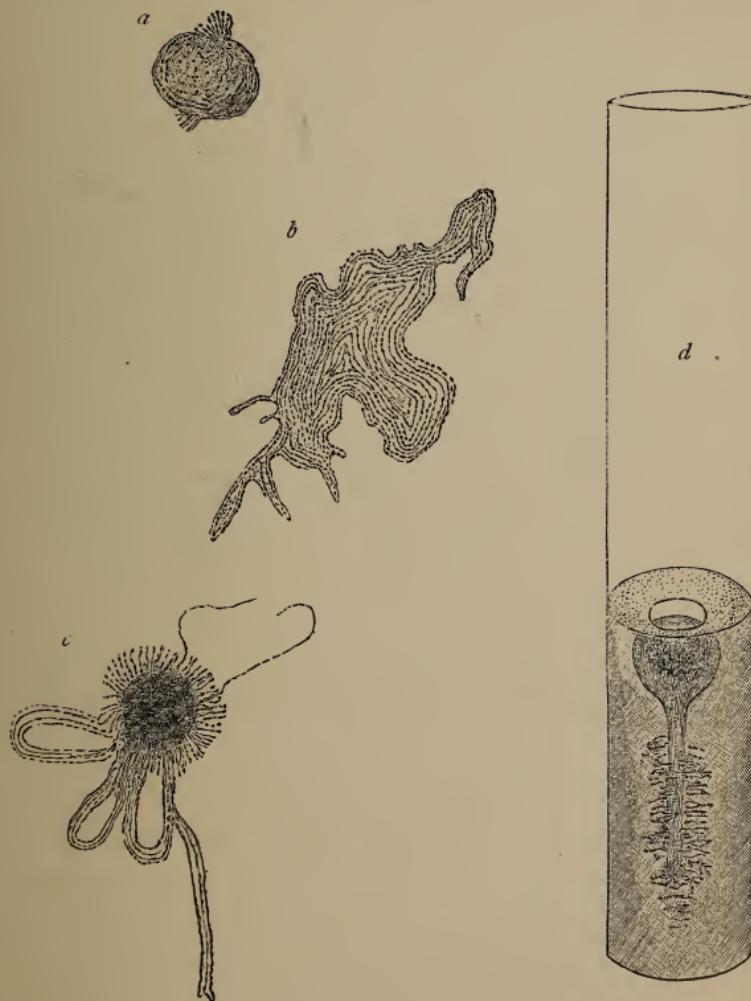

Fig. 17.—*Bacillus subtilis*: (a) small colony in the depth of the gelatine; (b) surface extension; (c) ditto; (d) growth in gelatine-tube.
(After Grace C. Frankland.)

into the space around. Although it likewise causes liquefaction of the gelatine, yet on comparing Fig. 16 *c* with Fig. 17 *d* the difference in its growth is at once apparent. In Fig. 18, at *a*, *b*, and *c* the organism is represented in its various stages of development; some of the thicker swollen forms visible at *b* and *c* indicating the process of spore-formation, whilst at *a* the bacilli are seen occurring singly

Fig. 18.—Various stages in the development of *b. subtilis*: (a) individual bacilli, also joined together; (b) swollen forms containing spore; (c) detached spores; (d) single bacilli, showing flagella.

and in chains. These figures represent the organism under the microscope magnified about one thousand times. Although I have only mentioned so far bacillar forms of microbes as occurring in the air, it must not be imagined that they are the prevailing forms found; on the contrary the micrococci moulds and yeasts often far outnumber them.

Micrococci are found hanging together in very characteristic fashions, sometimes in chains varying in length, when they are called *streptococci*, sometimes in pairs, as *diplococci* (see Fig. 19 *b*), and sometimes in packets of four and upwards, when they are known as *Sarcina*. In Fig. 19 *a* are seen such packets of cocci. The original organism was obtained from air collected on the roof of the Science Schools, South Kensington Museum.

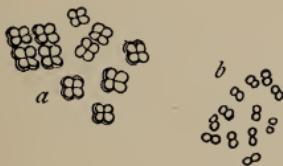

Fig. 19.—(a) *Sarcina*; (b) *Diplococcus*.

I have had a number of varieties of micro-organisms collected from the air, under more or less close observation, for upwards of six years, and it is exceedingly remarkable how constant and distinct, for one and the same organism, are the growths to which they give rise. Some of the colonies, especially, have often very beautiful and characteristic appearances, in many cases exhibiting magnificent patches of colour—deep orange, chrome

yellow, brown, various shades of red, green, black, etc. Often under a low magnifying power they are seen to spread over the surface of the gelatine, producing tangled networks of threads ; sometimes they resemble the petals of a flower, sometimes the roots of a tree, or its branches, constantly surprising the observer by the novelty and beauty of their modes of growth.

The investigations on aërial microbia, so far as they have as yet been carried, are of service in indicating how we may escape from all micro-organisms, whether harmful or harmless ; and, secondly, how we may avoid the conveyance of micro-organisms into the atmosphere from places where pathogenic forms are known or likely to be present. This acquaintance with the distribution of micro-organisms in general, and the power of controlling their dissemination which it confers, has led to the vast improvements in the construction and arrangement of hospital wards and of sick rooms generally, and has directed attention to the importance of avoiding all circumstances tending to disturb and distribute dust. It is, moreover, this knowledge of the distribution of micro-

organisms in our surroundings which has formed one of the foundations for the antiseptic treatment of wounds—that great step in surgery with which the name of Sir Joseph Lister is indelibly associated.

III.

MICRO-ORGANISMS IN WATER.

THE micro-organisms present in water have long been studied by direct observation with the microscope, but such observations can only be made in the case of foul waters in which bacterial life is very abundant, and even in such cases the information gained by the microscope alone has but little value. It is again to Dr. Robert Koch that we must acknowledge our indebtedness, who by introducing the beautiful process of "plate-cultivation," has rendered the greatest possible service in the investigation of a number of questions bearing on the micro-organisms in water. This method of plate-cultivation consists in taking some of the liquid or other substance under examination and mixing it with melted gelatine-peptone in a test-tube, the mixture being then poured out on a horizontal plate of glass and allowed to congeal, the plate being afterwards preserved in a damp

chamber at a suitable temperature. In some cases, instead of plates, it is more convenient to use circular glass dishes, similar to those employed in air-investigation. In the course of a few days the colonies make their appearance, and can be counted and further studied as required. (*See* Frontispiece.) By submitting a definite volume of water to this examination we can obtain a picture of the microbial contents of different waters, and are thus enabled to attack many interesting problems, amongst others to judge of the action upon such micro-organisms of various purifying processes, artificial and natural. One of the first things we find is that different kinds of water possess these aquatic forms in very different numbers. Thus the river Thames, in its raw condition, before undergoing any treatment at the hands of the water companies, has, on the average taken throughout an entire year, as many as 20,000 micro-organisms in one cubic centimetre (or about 20 drops) of water.

Now it used to be formerly supposed that the processes of purification as carried on at the works of the water companies, which consist in storage in large reservoirs with subsequent filtra-

tion through sand, were of little if any use at all. But on examining this same water after it has been in the hands of the water companies, I found that it contained, on delivery from the mains, in the same number of drops, on an average for the same period of time only 400. We have here then the efficiency of sand filtration put practically to the test, and the assurance that it forms a very material protective measure against our infection by water-carried microbes.

In deep-well water derived from the chalk, the numbers found are usually very small indeed. Thus, in the water obtained directly from the wells sunk into the chalk, I have found an average of 18. If this result, which, it must be remembered, has been obtained from water which has undergone no *artificial* filtration, but is the raw and untreated water as we find it, be contrasted with that mentioned above—viz., 20,000, which is the average for river waters, such as those of the Thames and Lee—it is at once apparent what an enormous difference there is in the microbial condition of these waters.

Thus, excellent as are the results obtained by the

artificial filtration of water through sand, yet they are even surpassed by the exhaustive filtration through vast thicknesses of porous strata such as is offered by chalk.¹ Pasteur has shown that it is not unfrequently the case for waters obtained from deep wells and deep-seated springs to be entirely destitute of organic life, or, in other words, quite sterile. But of a number of waters of this kind, I have only met with such as closely approached to this ideal state of things.

It might be anticipated that the samples of river-waters richest in micro-organisms would be those collected in the summer months, the higher temperature being more favourable to their growth and multiplication. The reverse is, however, the case; for the samples collected in the winter months were found to be, almost invariably, far richer in this respect. It must, however, be remembered that in summer the rivers are principally fed by

¹ In this connection I may refer the reader to the tables (taken from my reports to the Local Government Board) at the end of the book, showing the number of micro-organisms which I have found in the waters of the Thames and Lee before and after filtration, as well as in the deep-well water of the Kent Company.

spring-water, and receive comparatively little surface-drainage, whilst in winter the rivers are generally more or less in flood, and are swollen by large volumes of surface-water, which is naturally rich in micro-organisms.

Another very interesting point which has been brought into prominence in the course of such water investigations, is the power of multiplication possessed by micro-organisms either naturally present in water or artificially introduced for the purposes of observation and experiment. The following figures will give an idea of the activity of some microbes in this direction :—A sample of the Kent Company's deep-well water on the day of collection contained 7 in 20 drops ; after standing one day at 20° C. there were 21, and after being kept three days at the same temperature the numbers had risen to 495,000.

Again, on one occasion some ordinary distilled water, which is water as chemically pure as it can be rendered, was inoculated with a few drops of diluted urine, and the numbers determined, with the result that they rose from 1073 in one cubic centimetre to 48,100 after standing forty-eight

hours. A large number of experiments have also been made on the vitality of particular species of micro-organisms, more especially those associated with disease and called "pathogenic forms," in waters of different chemical composition, and I will briefly refer to a few of the results obtained.

Perhaps the most typical and well-defined of the micro-organisms connected with particular diseases is the *bacillus anthracis*, the exciting cause of malignant pustule or wool-sorters' disease in man, and splenic fever in cattle. I will not now enter into a detailed description of this microbe, as we shall have later on to become more intimate with it under the class of malignant micro-organisms. This bacillus on being introduced into ordinary drinking-water survives only a few hours, whilst its spores, as we should anticipate, are not in any way affected by such immersion, and retain their vitality, even in distilled water, for almost an indefinite length of time. In polluted water, such as sewage, on the other hand, not only do the bacilli not succumb, but they undergo extensive multiplication. Similarly Koch's "comma bacillus," so well known to us all as associated with Asiatic cholera, was

found to flourish in sewage, being still present in large numbers after eleven months' residence in this medium. In deep-well and filtered Thames water, on the other hand, although the "comma bacilli" were still demonstrable after nine days, they were only present in small numbers. Much less vitality is exhibited by the micrococcus of erysipelas when introduced into waters of various kinds, for even in sewage this organism could not be detected after the fifth day, whilst it could not survive a few hours' immersion in purer waters.

Quite recently an Italian has made some interesting investigations on the behaviour in different waters of the bacillus which produces that terrible disease called lockjaw or tetanus. He has found that whilst in distilled water it does not lose its virulent properties, if it is put into ordinary water in which other bacteria are present, its activity is weakened, recovering itself, however, as soon as the vitality of the other bacteria is diminished.

Sea-water, by reason of its chemical composition, causes a deterioration of the bacillus, but it regains its full degree of virulence as soon as it is restored to suitable conditions of temperature

and nourishment. This tetanus bacillus is then, as regards its immersion in water, a very hardy form of micro-organism, but we shall have later to consider its behaviour under other conditions, for much important light has been thrown upon the methods of successfully combating its pathogenic properties.

From these experiments it appears, therefore, that whilst as a rule ordinary drinking-water does not form a suitable medium for the extensive growth and multiplication of these particular pathogenic forms, yet, that in the condition of spores they are extremely permanent in any kind of water, however pure.

Before closing the subject of water-bacteria, it will be interesting to learn what is known about their presence in sea-water. Some very exhaustive and interesting experiments have been quite recently published by an American gentleman who made the Gulf of Naples the centre of his observations. Mr. Russell finds that the number present in ordinary sea-water is distinctly smaller than in the same volume of fresh water, and that their presence is not restricted to any particular

zone, but appears to be evenly distributed throughout the whole depth which was examined; but the contents of the mud at the bottom of the sea was invariably far richer in bacteria than the water in the immediate neighbourhood of the deposit; and that this increase was not occasioned by accretions from the land, but was due entirely to the growth and multiplication of the bacteria in the mud itself. For example, at a depth of about 400 feet, he found ten micro-organisms in a cubic centimetre of water; whereas in the mud in direct contact with this water as many as 200,000 were discovered in the same volume.

In connection with the suitability of such mud deposits for harbouring micro-organisms, it has been lately found that the mud at the bottom of the Lake of Geneva was very rich in microbes, and amongst them were found numerous pathogenic forms, whilst even more recently an investigator states that he has discovered the bacillus of tetanus in the mud at the bottom of the Dead Sea.

It is curious that whereas in air micrococci prevail, in water bacillar forms predominate. I

am tempted in conclusion to show you one water-organism, on account of the exquisite beauty and

Fig. 20.—*Bacillus arborescens*: (a) first appearance of colony growing on gelatine-plate; (b) more advanced stage; (c) individual bacilli taken from a broth-cultivation; (d) ditto taken from a gelatine cultivation. (After Grace C. Frankland.)

individuality of its growth on gelatine-plates. I found it originally in London water, and more recently in Loch Katrine and other upland waters, such as that of the river Dee, which is supplied to Aberdeen. In consequence of its characteristic appearance, I called it *bacillus arborescens*. When grown on gelatine-plates, already after twenty-four hours the colonies look, when seen with a low power under the microscope, like a branch with fine twigs growing from it at both ends; later on the "twigs" become much thicker and bushier, especially towards both ends, and finally they branch out in every direction, leaving only a small cloudy nucleus, whilst the gelatine in its immediate neighbourhood becomes soft, and assumes the appearance as seen in the figure. The bacillus itself gives rise to long and wavy threads when grown in broth-tubes (see Fig. 20 c). In the next figure are seen colonies in various stages of development formed by another water bacillus, viz. *b. violaceus*, so called on account of the violet-coloured pigment which it produces.

The interest attaching to the presence of micro-organisms in water originated principally in the

proof, which has been furnished by medical men, that some zymotic diseases are communicated through drinking-water. In the case of two diseases, at any rate, the evidence may be regarded as conclusive on the main point, and the communicability of Asiatic cholera and typhoid fever

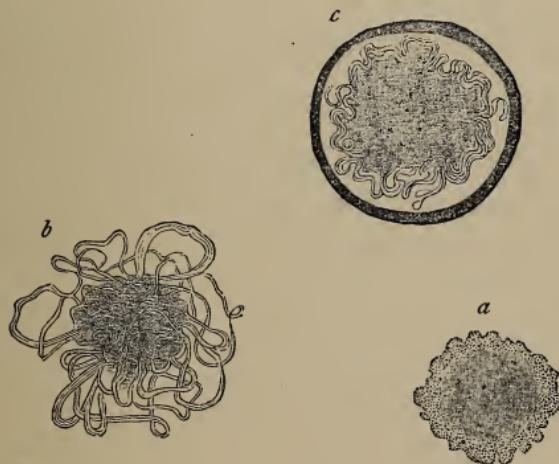

Fig. 21.—Colonies of *bacillus violaceus*: (a) colony in the depth of the gelatine; (b) thread-like ramifications extending in all directions; (c) later stage of development when the liquefaction of the gelatine has commenced. (After Grace C. Frankland.)

forms one of the cardinal principles of modern sanitary science, which year by year is becoming more widely recognized and generally accepted. The germ theory of zymotic disease, which has become more and more firmly established during

each successive decade of the past half-century, was naturally soon impressed into the service of those who sought to explain the empirical fact that these particular diseases are frequently communicated by water. It is significant that these views concerning the propagation of cholera and typhoid, and the importance to be, therefore, attached to drinking-water in connection with public health, are mainly English in origin, and were for many years unflinchingly preached and practised by English sanitary authorities, at a time when the germ theory of disease was a speculation, and not established as it now is.

The germ theory of disease having thus so early become interwoven with the consideration of potable waters, it is easy to understand with what eager interest the vigorous development in our knowledge of micro-organisms in general, and of their connection with disease in particular, which has taken place within the past fifteen years, has been watched by those who have had to devote much attention to the sanitary aspects of water-supply.

IV.

USEFUL MICRO-ORGANISMS.

WE must now turn our attention to some of the works of utility upon which many varieties of micro-organisms are continually engaged without rest day and night, and upon the fruit of which labours man is deeply dependent.

Amongst the vast array of chemical changes or chemical reactions, as we generally call them, which constitute the great science of chemistry, there is probably none which is so well known to the general public, and certainly none which enjoys a more ancient reputation and history, than the conversion of sugar into alcohol. There is hardly any race of men so primitive that they have not discovered the method of effecting this change, for to whatever part of the world we turn our attention, we find that in some shape or other a fermented liquid, or in other words an alcoholic liquid, is the favourite beverage of man.

But although the production of this substance has been known from the most remote times, the nature of this change from sugar to alcohol is still one of the obscurest in the whole of chemical science, is still one that the ingenuity and resource of man has been unable to imitate.

It was first found some fifty years ago by Cagniard Latour and Schwann, that the mysterious substance known to brewers as *yeast* or *barm* was really composed of a vast number of minute oval particles endowed with the powers of growth and multiplication, and, therefore, undoubtedly living. This substance, which was vulgarly known as yeast, having attracted the attention of scientific men, was in course of time rechristened, and received the more imposing, though less generally intelligible, title of *saccharomyces cerevisiae*. Comparatively little further progress was made in our knowledge of these minute forms of life until the alcoholic fermentation was submitted to the most exhaustive investigation by Pasteur, who spent many of the best years of his life in the study of these small oval particles of yeast. These memorable researches of Pasteur

showed that much of the success in brewing depends upon the use of pure yeast, free from other organisms; whilst by the more recent investigations of Christian Hansen, of Copenhagen, it has been found that it is not only necessary to employ yeast free from other organisms, but that for every particular kind of beer a particular kind of yeast and no other must be applied. This has led to what is known as the pure cultivation of yeasts for brewing purposes. This cultivation of pure yeasts requires the very greatest technical skill and scientific accuracy, and several special laboratories have been established for the purpose on the Continent. It is a most impressive sight to witness the careful preparation of these various pure yeast-growths, each yeast possessing particular virtues of its own which it will carry to any quarter of the globe to which it may be transmitted from the laboratory; for the advantages of these pure yeasts over the old haphazard mixtures are now becoming so widely recognized that numerous breweries in all parts of the world draw their supplies from these continental laboratories. These yeasts are divisible into two great classes for

practical purposes, according as they grow upon the surface or at the bottom of the liquid in which they are inducing the alcoholic fermentation. The *Top-Fermentation Yeasts* are those exclusively employed in the production of English, Scotch, and North German beers ; whilst the *Bottom-Fermentation Yeasts* are those used for the brewing of those South German and Austrian beverages which have in recent years acquired such great popularity in almost every part of the world as Lager Beer and Pilsen, and which are produced on such an enormous scale at Munich, and almost throughout the whole of Bavaria.

The following figure, which is reproduced from a micro-photograph, for which I am indebted to Dr. G. H. Morris, exhibits the characteristic appearance of yeast as employed in an English brewery.

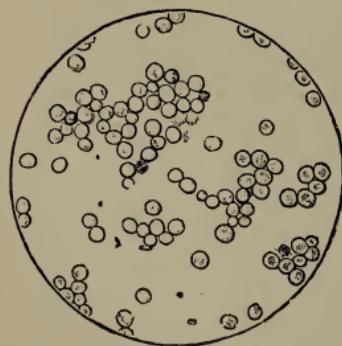

Fig. 22.—Microscopic Appearance of Brewers' Yeast.

But a mere microscopic inspection of this kind is quite inadequate to really distinguish between the different varieties of yeast, and it is to Hansen that the credit is due of having devised a series of tests to which they may be submitted in order that their individual characters may be ascertained.

Now, the principal consumer of alcohol is, as we know, Man ; for the lower animals evince no affinity for alcohol in any of its various forms, and to plant-life alcohol is actually fatal when administered in any considerable quantity. There is, however, one exception to this general antipathy manifested by the lower creation to this material which exercises such a mesmeric influence over the human race. We find, indeed, amongst the lowest of living organisms, amongst the bacteria, a single form the capacity for alcohol of which not only equals but far exceeds that of the most confirmed inebriate. The organism possessing this truly human instinct is a minute body presenting, when magnified 1000 times under the microscope, the appearance which you see in the following figure.

The existence and properties of this organism were first revealed by Pasteur, who gave it the name

of *Mycoderma aceti*. It has the property of taking up its abode in alcoholic liquids of moderate

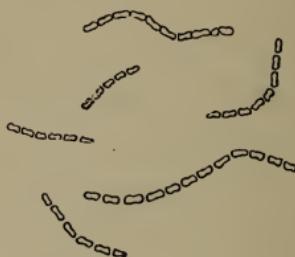

Fig. 24.—Vinegar Organism.

strength, and of there multiplying with extraordinary rapidity, consuming the alcohol and transforming it at a fabulous rate into that intensely sour substance known as acetic acid or vinegar. This organism is not, however, an undiscriminating dipsomaniac, grasping recklessly at anything which is alcoholic ; but on the contrary it refuses absolutely to have anything to do with spirituous liquids which are above a certain strength, viz., anything containing much above 10% of alcohol. That the wisdom of such an aversion to the stronger alcoholic drinks could be developed in mankind were indeed a consummation devoutly to be wished !

Through the agency of this small organism the wine prepared according to the most approved methods from the choicest vintages, matured for years in the best cellars in cask and bottle, is converted in the course of a few hours into a sour liquid, and its value reduced from shillings to as many pence.

It is, however, with regard to the bacteria connected with other industries than those of alcoholic fermentation that our knowledge has particularly advanced during the last few years. Thus some of the chief phenomena in agriculture have recently received a most remarkable elucidation through the study of bacteria. Perhaps the most striking changes which micro-organisms bring about are those in connection with animal and vegetable matter. Under ordinary circumstances these animal and vegetable matters undergo putrefaction and decay, or, in common parlance, they "go bad." Formerly it was supposed that this "going bad" was an inherent property of such substances, but it is now known to be entirely due to the action of various micro-organisms; and if due precautions be taken to exclude these micro-

organisms, vegetable and animal substances are found to be almost quite permanent. Therefore, but for the agency of bacteria, the surface of the earth would be covered with the remains of plants and animals undergoing but little more change than the stones and other mineral ingredients of which the earth's crust is composed. But under these circumstances life, as we now know it upon the surface of the globe, would soon come to an end, for it is by the decomposition of refuse animal and vegetable matter in the ground that the fertility of the soil is maintained, and in the absence of this decomposition, which, as I have said, can only be effected by the agency of micro-organisms, the most fertile land would soon become a barren waste, incapable of supporting plant-life ; and upon the extinction of the latter the cessation of animal-life would rapidly follow as a necessary consequence.

Thus, whilst the animal is directly dependent upon the vegetable kingdom, the latter owes its sustenance to the products elaborated by micro-organisms from refuse animal and vegetable matters ; and if one link, although at first sight

perhaps the least important one in the chain, be broken, the whole mechanism, with its wonderful cycle of changes, must necessarily collapse.

Scientific agriculturists are generally agreed that one of the most important plant-foods in the soil is *Nitric acid*; indeed they inform us that if a soil were utterly destitute of this material, it would be incapable of growing the barest pretence of a crop either of corn, or of roots, or of grass, even if the soil were in other respects of the most superb texture, however favourably it might be situated, however well drained, tilled, and supplied with the purely mineral ingredients of plant-food, such as *potash, lime, and phosphoric acid*.

Yet notwithstanding the commanding importance of this substance, nitric acid, to vegetation, it is present in ordinary fertile soils in but little more than the most minute doses. These facts are gathered from the important experiments which have during the past half-century been going on at Rothamsted, under the direction of Sir John Lawes and Dr. Gilbert. Now the cause of such minute quantities only of nitric acid being found in soils is due partly to this material being washed

away by the rain, and partly to its being so eagerly taken up by plants for the purposes of nutrition; for it has long been known that by suitable means the quantity can be enormously increased if no vegetation is maintained, and the ground properly protected from rain. The soil in fact, under ordinary circumstances, continuously generates this nitric acid from the various nitrogenous manures which are applied to it, and it is in the form of nitric acid that the nitrogen of manures principally gains access as nutriment to the plant.

It was in the year 1877 that two French chemists, Schloesing and Müntz, showed that this power of soils to convert the nitrogen of nitrogenous substances into nitric acid was due to low forms of life—to micro-organisms or bacteria. Since that time many interesting facts have been elucidated by Warington, Munro, and others, but the particular organism responsible for this important reaction succeeded in eluding all attempts at its identification and isolation. The details of the many efforts which were made in this direction by different investigators would occupy too much time to describe. Suffice it to say that in

1890 this organism was at length isolated, and that about a month after I had succeeded in separating it out, Winogradsky, who had also been working at the same subject, announced his discovery of a very similar if not identical nitrifying organism.

Fig. 25.—Nitrifying organism (*Percy Frankland*) possessing the power of converting ammonia into nitrous acid.

The difficulty of obtaining this organism in a state of purity was enhanced by its inability to grow upon any of the usual culture-media employed, requiring for its growth an entire absence of all organic matter. In fact I have kept it alive in purely mineral solutions for upwards of four years. It has, moreover, been proved by Winogradsky, beyond all reasonable doubt, that the nitrifying organisms not only flourish, but multiply, and actually build up living protoplasm in a solution from which organic matter has been most rigorously excluded. If these experiments are correct, they are subversive of one of the fundamental principles of vegetable physiology, which denies to all living structures, save those of green plants

alone, the power of building up protoplasm from such simple materials.

But these discoveries had not completely unravelled the problem of nitrification, for the organisms thus separated out were found to possess only the property of *converting ammonia into nitrous and not into nitric acid*. The nitrous acid is an intermediate body which curiously is rarely found excepting in very minute quantities in soil, and the conversion of ammonia into nitrous acid is accomplished with far more difficulty by *purely chemical means* than the conversion of the latter into nitric acid, which can be done in the laboratory with the greatest facility.

But how then is the nitric acid found in the soil produced, when these organisms yield only nitrous acid? At the time when I found that the organism which I had isolated produced only nitrous acid, I pointed out that it was doubtless explicable on one of two hypotheses. (1) That nitrous and nitric acids are produced by totally distinct organisms, or (2) that the same organism produces the one or the other according to the conditions under which it is growing.

More recent researches of Warington and Winogradsky have shown that the first of these two alternative hypotheses is the correct one, for by making cultivations of soil in a solution containing nitrous acid and no ammonia, a micro-organism has been isolated which possesses the power of converting nitrous acid into nitric acid, but has no power of attacking ammonia.

The process of nitrification in the soil now becomes intelligible in its entirety ; it is the work of two independent organisms, the first of which converts ammonia into nitrous acid, whilst the second transforms into nitric acid the nitrous acid produced by the first.

Both of these bacteria refuse to grow on the ordinary solid cultivating media employed by bacteriologists ; this difficulty has, however, been overcome in a most ingenious manner, originally devised by Professor Kühne, in which the solid medium is composed of mineral ingredients, the jelly-like consistency being obtained by means of Silica. By means of this Silica-jelly colonies of the nitrifying organism have been obtained, as in

the case of other micro-organisms with ordinary gelatine-peptone.

There is a point in connection with the distribution of nitric acid in nature which is exceedingly remarkable, and which forces itself upon the attention of every student of the process of nitrification. Although nitric acid is generally so scantily present in the soil, there is one notable exception to this rule, for in the rainless districts of Chili and Peru there are found immense deposits of nitrate of soda, or Chili-saltpetre as it is called, which would appear to represent the result of a gigantic nitrification process in some previous period of the earth's history. The vast quantities of this material which occur in these regions of South America can be gathered from the fact that its exportation has for years been going on at the rate indicated by the following figures:—During the first six months of 1890 there were brought to

The United Kingdom ...	90,000 tons
The European Continent	480,000 ,

From the presence of such altogether enormous quantities, one is almost tempted to hazard the

suggestion that in this particular region of the earth, under some special circumstances of which we know nothing, the nitrifying organisms must have been endowed then and there with very much greater power than they possess to-day, and it is particularly noteworthy that in a recent examination of soils from nearly all parts of the earth, one coming from Quito, and therefore not far distant from these nitrate-fields, was found to possess the power of nitrification in a degree far beyond that exhibited by any other soil hitherto experimented with. Is it not possible, perhaps, that we have in these vigorous nitrifying organisms of the soil of Quito the not altogether unworthy descendants of that Cyclopean race of nitrifying bacteria which must have built up the nitrate wealth of Chili and Peru, and which thus countless ages ago founded the fortunes of our Nitrate Kings of to-day?

But whilst the study of the bacteria giving rise to nitrification has thus led to the subversion of what was regarded as a firmly-established principle of vegetable physiology (*viz. the incapacity of any*

but green plants to utilize carbonic acid in the elaboration of protoplasm), the same science has received another shock of perhaps equal if not greater violence through researches which have been carried on with other micro-organisms flourishing in the soil.

For nearly a century past agricultural chemists and vegetable physiologists have been debating as to whether the free nitrogen of our atmosphere can be assimilated or utilized as food by plants. This question was answered in the negative by Boussingault about fifty years since; the problem was again attacked by Lawes, Gilbert, and Pugh about thirty years ago, and *their* verdict was also to the same effect. In the course, however, of their continuous experiments on crops, Lawes and Gilbert have frequently pointed out that whilst the nitrogen in most crops can be accounted for by the combined nitrogen supplied to the land in the form of manures and in rain-water, yet in the case of particular *leguminous* crops, such as peas, beans, vetches, and the like, there is an excess of nitrogen which cannot be accounted for as being derived from these obvious sources.

The origin of this excess of nitrogen in these particular crops they admitted could not be explained by any of the orthodox canons of the vegetable physiology of the time. The whole

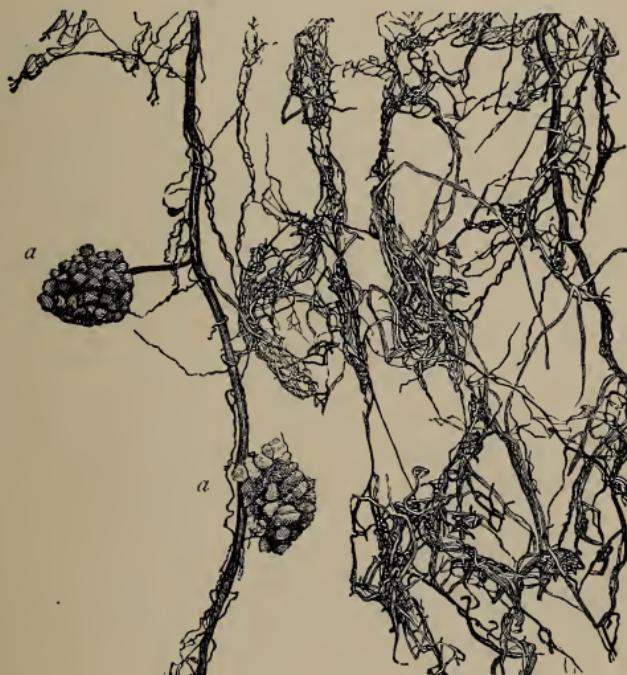

Fig. 26.—Roots of Sainfoin. (*Lawes and Gilbert.*) (a) Nodules.

question of the fixation of atmospheric nitrogen by plants was again raised in 1876 by a very radical philosopher, in the person of M. Berthelot, whilst the most conclusive experiments

were made on this subject by two German investigators, Professor Hellriegel and Dr. Wilfarth, who have not only shown that this excess of nitrogen in leguminous crops is obtained from the atmo-

Fig. 27.—Roots of Sainfoin. (*Lawes and Gilbert.*) (a) Nodules.

sphere, but also that this assimilation of free nitrogen is dependent upon the presence of certain bacteria flourishing in and around the roots of these plants, for when these same plants are cultivated in sterile

soil the fixation of atmospheric nitrogen does not take place. Moreover, the presence of these microbes in the soil occasions the formation of

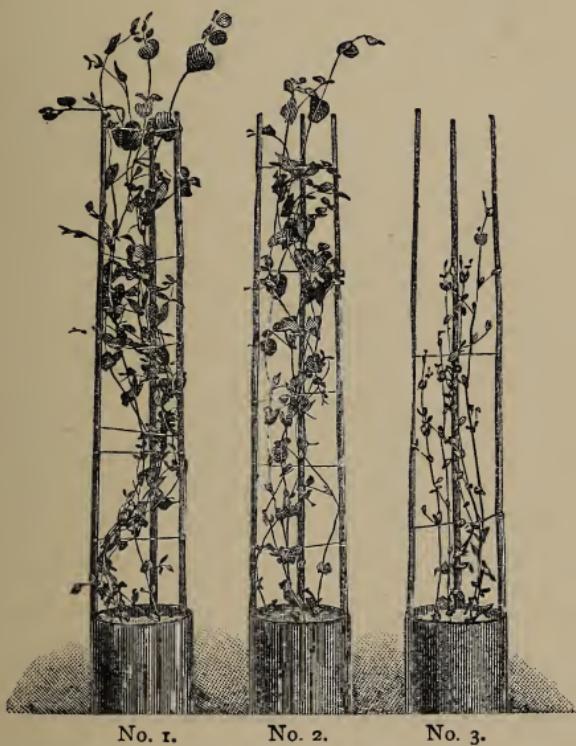

Fig. 28.—Pea-Plants. (*After Nobbe.*) No. 1. Inoculated with pure cultures from tubercles of pea. No. 2. Inoculated with pure cultures from tubercles of lupin. No. 3. Inoculated with pure cultures from tubercles of robinia. The inoculations were all made on August 14th, 1890, and the plants photographed on October 9th, 1890.

peculiar swellings or tuberosities on the roots of these plants, and these tuberosities which are not

formed in sterile soil are found to be remarkably rich in nitrogen and swarming with bacteria.

Extremely important and instructive are the experiments of Professor Nöbbe, who has not only confirmed the results mentioned, but has endeavoured to investigate the particular bacteria which bring about these important changes, and he has indeed succeeded in showing that in many cases each particular leguminous plant is provided with its particular micro-organism which leads to the fixation of free-nitrogen. Thus, he found that if pure cultivations of the bacteria obtained from a pea-tubercl^e were applied to a pea-plant, there was a more abundant fixation of atmospheric nitrogen by this pea-plant than if it was supplied with pure cultures of the microbes from the tubercles of a lupin or a robinia, whilst similarly the robinia was more beneficially affected by the application of pure cultures from robinia-tubercl^es than by those from either pea-tubercl^es or lupin-tubercl^es.

To micro-organisms again then we must ascribe the accomplishment of this highly important chemical change going on in the soil, although it

has not hitherto been so fully illuminated as the process of Nitrification.

Before passing on to some of the other works of a less friendly character, for which we are indebted to micro-organisms, I should like to draw your attention to a very remarkable and important characteristic possessed in general by these lowly forms of life. Any of the ordinary plants and animals with which we are familiar may be regarded as analytical machines, and we ourselves, without any knowledge of chemistry, are constantly performing analytical tests ; thus we can all distinguish between sugar and salt by the taste, between ammonia and vinegar by the smell, whilst by a more elaborate investigation we distinguish, for instance, between the milk supplied from two different dairies by ascertaining on which we or our children thrive best. In fact such analytical or selective operations are amongst the first vital phenomena exhibited by an organism on coming into this world. It is, however, particularly surprising to find this analytical or distinguishing capacity developed in an extraordinarily high

degree amongst micro-organisms. From the power which we have seen that some possess of flourishing on the extremely thin diet to be found in distilled water, we should be rather disposed to think that caprice would be the very last failing with which they would be chargeable. As a matter of fact, however, the perfectly unfathomable and inscrutable caprice of these minute creatures is amongst the first things with which the student of bacteriological phenomena becomes impressed. Let me call your attention to a striking example of this which I have recently investigated.

Here are two substances which have the greatest similarity—

	<i>Mannite.</i>	<i>Dulcite.</i>
<i>Occurrence</i>	... numerous plant-juices	ditto, but less frequently.
<i>Taste</i> ...	sweet ...	ditto, but less so.
<i>Melts</i> ...	166° C.	188° C.
<i>Crystalline form</i>	large rhombic prisms	large monoclinic prisms.

Now, not only do these two substances possess such a strong external resemblance to each other, but in their chemical behaviour also they are so closely allied that one formula has to do duty for both of them ; so slight is the difference in the manner in which their component atoms are arranged, that

chemists have not yet been able with certainty to ascertain in what that difference consists. Under these circumstances it would have been anticipated that bacteria would be quite indifferent as to which of these two substances was presented to them, and that they would regard either both or neither as acceptable. But such is by no means the case ; some micro-organisms, like ordinary yeast, have *no action upon either*, whilst *others will attack both*, and

Fig. 32.—*Bacillus ethaceticus*. (After Grace C. Frankland.)

others will attack mannite, leaving dulcrite untouched, while representatives of a fourth possible class, *which would act upon dulcrite but not upon mannite*, are as yet undiscovered.

The accompanying figure shows an organism which I discovered to be capable of acting upon mannite but not on dulcrite. I have christened it *Bacillus ethaceticus*, because of the substances which it yields during its fermentative action on various materials.

Again, more recently I have, in conjunction with Mr. Frew, succeeded in obtaining a micro-organism which decomposes both mannite and dulcite, and which has received, also on account of the products which it yields, the somewhat unwieldy title of *Bacillus ethacetosuccinicus*.

But these are by no means the ultimate limits

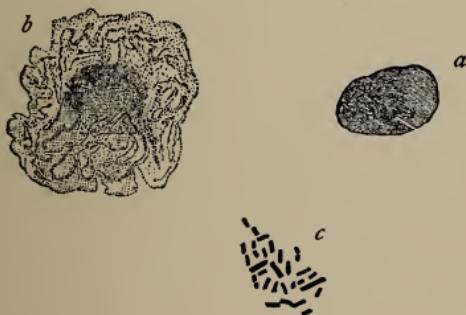

Fig. 33.—*Bacillus ethacetosuccinicus*. (a) Colony in the depth of the gelatine. (b) Colony on the surface. (c) Individual bacilli. (After Grace C. Frankland.)

to which the selective or discriminating powers of micro-organisms can be pushed, for although mannite and dulcite are extremely similar substances, they are not chemically identical. We are acquainted, however, with substances which, though chemically identical, are different in respect of certain physical properties only, and are

hence known as *Physical Isomers*. It is in explanation of this physical isomerism that one of the most beautiful of chemical theories was propounded by Lebel and Van 't Hoff, in 1874, and remains unsupplanted to the present day.

This theory depends upon taking into consideration the dissymmetry of the molecule, which is occasioned by the presence in it of a carbon-atom, which is combined with four different atoms or groups of atoms.

This molecular dissymmetry is specially exhibited in the crystalline form of such substances, and in their action upon polarized light.

The molecule arranged according to the one pattern has the property of turning the plane of polarization in one direction, whilst the molecule arranged according to the other pattern has invariably the property of turning the plane through precisely the same angle in the opposite direction. The molecular dissymmetry ceases when two such molecules combine together, the resulting molecule having no action on polarized light at all.

The interest of these phenomena in connection

with micro-organisms lies in the fact that they are sometimes possessed of the power of discriminating between these physical isomers. Although this remarkable property was demonstrated years ago by Pasteur in respect of the tartaric acids, it has only comparatively rarely been taken advantage of. Recently, however, chemical science has been enriched in several instances by successfully directing the energies of micro-organisms in such work of discrimination.

During the past few years no chemical researches have commanded more interest, both on account of their theoretic importance and the fertility of resource exhibited in their execution, than those of Emil Fischer, which have led to the artificial preparation in the laboratory of several of the various forms of sugar occurring in nature, as well as of other sugars not hitherto discovered amongst the products of the animal or vegetable kingdoms. The ordinary natural sugars are all bodies with dissymmetric molecules, powerfully affecting the beam of polarized light, but when prepared artificially they are without action on polarized light, because in the artificial product the left-handed

and right-handed molecules are present in equal numbers, the molecules of the one neutralizing the molecules of the other, and thus giving rise to a mixture which does not affect the polarized beam either way. By the action of micro-organisms, however, on such an inactive mixture, the one set of molecules are searched out by the microbes and decomposed, leaving the other set of molecules untouched, and the latter now exhibit their specific action on polarized light, an active sugar being thus obtained.

The most suitable micro-organisms to let loose, so to speak, on such an inactive mixture of sugar-molecules, are those of brewers' yeast, which decompose the sugar-molecules with formation of alcohol and carbonic anhydride. Their action on these inactive artificial sugars of Fischer's is particularly noteworthy.

One of the principal artificial sugars prepared by Fischer is called *fructose*; it is inactive, but consists of an equal number of molecules of oppositely active sugars called *laevulose*.

One set of these laevulose-molecules turns the plane of polarization to the right, and we may

call them *right-handed laevulose*, whilst the other set of *laevulose-molecules* turns the plane of polarization to the left, and we may call them *left-handed laevulose*.

The left-handed laevulose occurs in nature, whilst the right-handed laevulose, as far as we know, does not. Now, on putting brewers' yeast into a solution of the fructose, the yeast-organisms attack the left-handed laevulose-molecules and convert them into alcohol and carbonic anhydride, whilst the right-handed laevulose is left undisturbed. The yeast-organisms thus attack that particular form of laevulose of which their ancestors can have had experience in the past, whilst they leave untouched the right-handed laevulose-molecules, which, being a new creation of the laboratory, they have no hereditary instinct or capacity to deal with.

This selective power is possessed also by other forms of micro-organisms besides the yeasts, which are indeed only suitable for the separatory decomposition of sugars, and by means of bacterial forms a much greater variety of substances can be attacked in this manner. Thus I have lately found

that glyceric acid can be decomposed by the *B. ethaceticus* already referred to.

This glyceric acid should, according to Lebel and Van 't Hoff's theory, be capable of existing in two physically isomeric forms.

The ordinary glyceric acid known to chemists is, however, quite inactive to polarized light, and must consist, therefore, of a combination in equal molecules of a right-handed and left-handed glyceric acid. Now when the *B. ethaceticus* is put into a suitable solution of the calcium salt of this glyceric acid, it multiplies abundantly, and completely consumes the right-handed molecules of the salt, but leaves the left-handed molecules entirely intact, and thus I was able to obtain for the first time a powerfully active glyceric acid.

But I must not allow the fascination attaching to the idiosyncrasies of micro-organisms to encroach too much upon our time, and must omit many other interesting and beautiful instances of this selective action, on account of their being possibly too technical in their character to excite general interest. I cannot, however, resist in

conclusion drawing your attention to the manner in which these idiosyncracies may be changed, and the way in which their individuality may be affected by judicious treatment.

Although micro-organisms are becoming more and more indispensable re-agents in the chemical laboratory, essential as they are for the production of many bodies, it is always necessary to bear in mind that by virtue of their vitality their nature is infinitely more complex than that of any inanimate chemicals which we are accustomed to employ. In a chemically pure substance we believe that one molecule is just like another, and hence we expect perfect uniformity of behaviour in the molecules of such a pure substance, under prescribed conditions. In a pure cultivation of a particular species of a micro-organism, however, we must not expect such rigid uniformity of behaviour from each of the individual organisms making up such a cultivation, for there may be and frequently are great differences amongst them, in fact each member of such a pure culture is endowed with a more or less marked individuality

of its own, and these possible variations have to be taken into consideration by those who wish to turn their energies to account. In fact, experimenting with micro-organisms partakes rather of the nature of legislating for a community than of directing the inanimate energies of chemical molecules.

Thus frequently the past history of a group of micro-organisms has to be taken into account in dealing with them, for their tendencies may have become greatly modified by the experiences of their ancestors. In support of this I will mention the following instance, which recently came under my observation. Some time ago I came upon a bacillus which has the property of fermenting calcium citrate, and I have found that it can go on exerting this power for years. But if it is plate-cultivated, or in other words if we induce it to grow on gelatine-peptone, and take one of the resulting colonies and transfer it to a sterile solution of calcium citrate, identical in every way to that which before it readily fermented, *it invariably fails to set up any fermentation*, the bacillus

having thus, by mere passage through the gelatine medium, lost its power to produce this effect. If, however, we take another similar colony and put it into a solution of broth containing calcium citrate, fermentation takes place ; on now inoculating from this to a weaker solution of broth containing calcium citrate this also is put into fermentation, and by proceeding in this manner we may ultimately set up fermentation in a calcium citrate solution, which absolutely refused to be fermented when the bacilli were taken directly from the gelatine plate.

Phenomena of this kind clearly indicate that there may be around us numerous forms of micro-organisms, of the potentiality of which we are still quite ignorant ; thus, if we were only acquainted with the bacilli I have just referred to from gelatine cultures, we should be quite unaware of their power to excite this fermentation of calcium citrate, which we have only been enabled to bring about by pursuing the complicated system of cultivation I have described. It is surely exceedingly probable, therefore, that many of the micro-organisms with

which we are already acquainted may be possessed of numerous important properties which are lying dormant until brought into activity by suitable cultivation.

The power of modifying the characters of bacteria by cultivation is, I venture to think, of the highest importance in connection with the problems of evolution, for in these lowly forms of life in which, under favourable circumstances, generation succeeds generation in a period of as little as twenty minutes, it should be possible, through the agency of selection, to effect metamorphoses, both of morphology and physiology, which would take ages in the case of more highly-organized beings to bring about.

We hear much from the enthusiastic apostles of education about the possibility of altering the human race through a suitable course of training, but even the most sanguine of these theorists cannot promise that any striking changes will be effected within several generations, so that such predictions cannot be tested until long after these reformers have passed away.

In the case of micro-organisms, however, we can study the effect of educational systems consequentially pursued through thousands of generations within even that short span of life which is allotted to us here.

V.

MALIGNANT MICRO-ORGANISMS.

THE properties of micro-organisms which we have hitherto considered have been harmless or even beneficial to man ; there are, however, a number of varieties of microbes whose behaviour is anything but amiable, and whose dangerous character has brought such discredit upon the entire class of micro-organisms, that the virtues of some are often overlooked, and their usefulness forgotten, owing to the terror and dismay which their harmful brethren inspire. For, as you know, some of them exist as parasites on the higher organisms, including man himself ; of these higher organisms they frequently cause the degeneration and death, producing the severest diseases amongst animals high and low, and threatening mankind with the most murderous plagues and epidemics. We have already learnt to call such mischievous

varieties *Pathogenic*, whilst we usually call the diseases to which they give rise *Zymotic*, in consequence of their course presenting more or less resemblance to a process of fermentation. Thus, the manner in which infectious diseases are communicated, the continuous propagation of the infectious principle through a long series of individuals, the occasional transportation of the infection to long distances; again, the period of incubation, and the typical manner in which these diseases run their course, all are circumstances which have long and irresistibly impressed observers with the organized or living nature of the exciting cause.

In fact, although we are firmly convinced that all the zymotic diseases, such as cholera, scarlet fever, typhoid fever, measles, small-pox, diphtheria, hydrophobia, etc., are due to the activity of micro-organisms, yet it is in comparatively few cases that particular micro-organisms have been conclusively proved to be the cause of a particular disease.

We will now turn our attention to some of the cases in which diseases have been traced to the agency of micro-organisms,

The disease which of all others has been most thoroughly studied in this respect is one which we have already had occasion to mention, viz. *Wool-sorts' Disease*, or *Malignant Pustule*; it is much dreaded also by farmers, owing to the ravages which it makes among stock, the particular disease in cattle being known as *Splenic Fever*. It was in the year 1850 that two French doctors, Rayer and Davaine, first stated that they had found small, rod-like bodies in the blood of subjects whose death was due to anthrax. These are the words in which they announce this most important discovery :—“On trouve dans le sang de petits corps filiformes ayant environ le double en longueur du globule sanguin. Ces petits corps n'offrent point de mouvement spontané.”

But here the matter rested, for no further notice was taken of these “petits corps filiformes,” and this indifference lasted for upwards of twelve years, until in 1863 attention was again directed to these mysterious forms, in consequence of the public interest which was attracted by the researches of Pasteur.

It was not until the year 1877 that Pasteur, in

a memoir read before the Academy of Sciences of Paris, demonstrated beyond all doubt that these small, rod-like bodies, first observed by Davaine and Rayer in 1850, were the sole exciting cause of anthrax. Since that time our acquaintance with these bacilli has been greatly extended by Robert Koch and others, and our knowledge of their life-history confirmed by the most exhaustive and careful investigations. These researches are still continuing, and we shall see later on to what wonderful results they have led in combating the symptoms to which their presence gives rise.

But we will now examine a little more in detail how this disease is communicable from animal to man.

If the blood taken from any part of an animal just dead of anthrax be microscopically examined, it will be found to be teeming with these bacillar forms. Now, if the smallest quantity of such blood is introduced into the tissues of another animal capable of taking the disease, the inoculated animal becomes infected, and almost certainly succumbs ; and if now the blood of this second victim be similarly examined, this also will be

found densely populated with the same bacilli. We thus see that the disease is accompanied by the enormous multiplication of the micro-organism within the system of the victim, and that the disease may be indefinitely communicated from one animal to another.

But we may also cause this bacillus to grow and multiply abundantly outside the animal system altogether, or, as we term it, *cultivate the organism in an artificial medium*. Thus, if we take on the point of a needle the minutest trace of the blood of an animal dead of splenic fever, and then introduce the point of the needle into any of the ordinary cultivating media, such as broth, gelatine-peptone, agar-agar,¹ or blood-serum, we shall obtain in the course of a few days an abundant growth of the anthrax bacillus, readily visible to the naked eye. I have before referred to the highly characteristic appearances to which this organism gives rise on being artificially cultivated. In the accompanying figures some of these appearances are illustrated. In Fig. 34 *a* we see one of these

¹ Japanese isinglass, capable of remaining solid at a higher temperature than ordinary gelatine.

anthrax colonies greatly magnified, growing on the surface of a gelatine-plate. The peculiar wavy bands and whip-like projections remind us of the colonies of *bacillus subtilis*. Fig. 34 *b* repre-

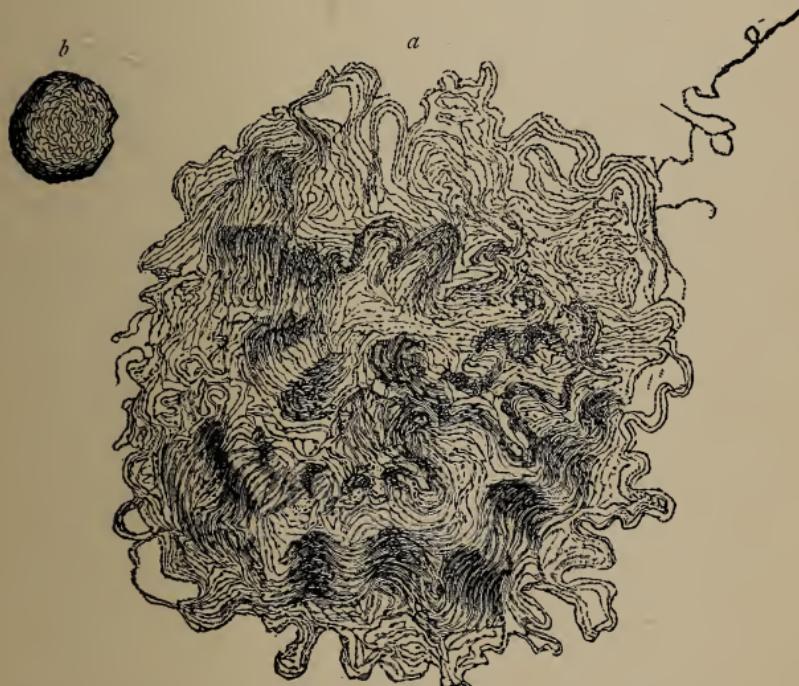

Fig. 34.—Colonies of Anthrax bacilli. (a) Surface colony much enlarged ; (b) Small depth colony. (After Flügge.)

sents a younger anthrax colony growing in the depth of the gelatine before it has come to the surface. Fig. 35 *a* and *b* shows the individual bacilli growing singly and in long vermiciform threads ; at

c spores are also visible. In the blood of the subject affected these anthrax bacilli are not able to form spores, but outside the body they give rise abundantly to these indestructible forms, and it is this power of producing spores which renders this organism so dangerous and persistent. Thus, if the carcasses of animals dead of anthrax are buried, or are allowed to decay upon the surface

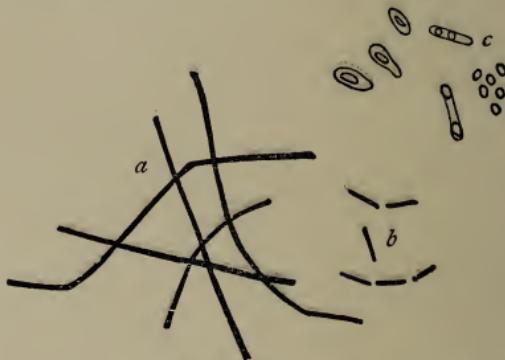

Fig. 35.—Anthrax bacilli. (*a* and *b*) individual bacilli growing singly and in threads; (*c*) spores.

of the earth, the bacilli form spores in the soil, and healthy animals may thus become infected by taking in the spores with their food when grazing.

Again, the skins of animals which have died of anthrax not unfrequently pass into commerce, and often prove fatal to the tanners and wool-sorters who handle them, even long afterwards.

From this it will be seen how necessary it is that the strictest supervision should be exercised whenever an outbreak of splenic fever takes place, and that the disposal by cremation of the carcases of the affected animals should be most rigorously enforced. Unfortunately, those most closely concerned with this disease are only too often quite ignorant of its dangers. Thus, during a recent outbreak of this disease in a rural district of England, the butcher to whom the slaughtering of the affected animals was intrusted, was quite unaware of the dangerous task upon which he was engaged, and only had his ignorance enlightened by himself falling a victim to the disease.

We must now turn to another disease which is far more common in man than anthrax, but which, like anthrax, is also caused by a micro-organism—in this case a micrococcus, not a bacillus. The micrococci of this disease—erysipelas—hang together in chains, and are therefore known as streptococci (Fig. 36).

These organisms can be easily cultivated in artificial media outside the body, and there can be no doubt that the organism is the cause of the

disease, for erysipelas has actually been produced in man by intentionally inoculating these cultivations of the streptococcus, with the result that typical erysipelas was produced. I should mention that these experiments upon human beings were performed, not merely for the purpose of scientific inquiry, but also for the benefit of the persons inoculated, who were suffering from malignant tumours, which are sometimes alleviated by an attack of erysipelas. Owing to these experiments,

Fig. 36.—Streptococcus of Erysipelas.

therefore, we are able with confidence to affirm that this particular organism is not only capable of setting up erysipelas in animals but also in man.

But, undoubtedly, the greatest and most remarkable piece of work which has ever been accomplished in connecting disease with the life of micro-organisms, is the proof which has been furnished by Koch of the exciting cause of tuberculosis, one of the most familiar forms of which,

pulmonary consumption, is the commonest disease in the world, and in this country the greatest enemy to human life, destroying as it does about one-fifth of our population, generally in the best and most active years of existence. This disease, we now know with absolute certainty, is caused by a minute bacillus, which is invariably found in all the varieties of tuberculous disease. By the most ingenious methods this bacillus has been

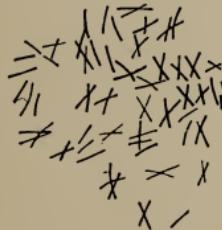

Fig. 37.—Bacillus of Tuberculosis. (*After Koch.*)

cultivated in artificial media outside the body, and whenever reintroduced into the system of an animal it again produces the characteristic disease.

The exact manner in which this disease is communicated from one individual to another has not been actually ascertained; but when it is borne in mind that the sputum of consumptive patients almost always contains the organism, and that the bacillus is known to produce spores, it is not

difficult to understand that there must be very numerous channels by which the poison may be conveyed. It would appear, however, that the mere conveyance of the organism from one person to another is not sufficient to induce the disease, but that more or less predisposition to the disease is also necessary. In the case of all the zymotic diseases, predisposition no doubt plays an important part in the process of infection, but in the case of tuberculosis this factor of predisposition appears to be of more than usual importance.

The possibility of this disease being communicated from the lower animals to man must also be borne in mind, for tuberculosis is comparatively common amongst cattle, and, as in so many other infectious diseases, milk must be viewed with suspicion as a particularly suitable medium for the conveyance of the zymotic poison.

Of immense importance is the identification within the last few years of the specific cause of tetanus, or lockjaw. Ever since Carle and Rattone proved, in the year 1884, that tetanus was a disease capable of being communicated from one subject to another, inasmuch as rabbits

inoculated with pus taken from the infected part of a man who had died of tetanus also succumbed to the same disease, numerous investigators have been attracted towards this field of inquiry. Nicolaier was the first to discover that certain bacilli, widely distributed in the superficial layers of soil, were capable, when subcutaneously inoculated into mice, guinea-pigs, and rabbits, of setting up symptoms typical of tetanus from which they subsequently died. These results were confirmed by Rosenbach, but all endeavours to procure the bacillus in a pure condition, free from other micro-organisms, failed, until Kitasato, a Japanese pupil of Dr. Koch, hit upon the following ingenious plan, by which he successfully isolated the tetanus-bacillus. Kitasato took some tetanus-pus and inoculated it on to agar-agar, and kept it at a temperature of about 38° C. in an incubator; already, within the space of twenty-four hours, an abundant growth was visible, and on examining some of this under the microscope he found various micro-organisms, and amongst them bacilli which he at once recognized as those identified with tetanus by Nicolaier and others.

These bacilli form spores at the end of the rod, resembling a club in appearance. (The accompanying figure is taken from Kitasato's original paper, in which he describes the tetanus-bacillus.) They are strictly anaërobic, that is, refuse to grow

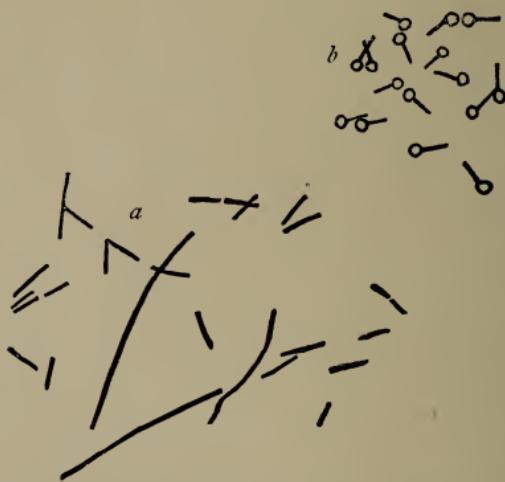

Fig. 38.—Bacilli of Tetanus or Lockjaw. (a) individual bacilli; (b) spores. (After Kitasato.)

in the presence of air, and hence the difficulties which arose in obtaining them in a pure state.

Now at the end of forty-eight hours these characteristic club-shaped spore-bacilli had increased enormously, and the vessel containing the cultivation was then placed in water already heated to 80° C. and maintained at that temperature during a

period of three-quarters to one hour. On examining the growth afterwards, everything was found to have been killed off except the spores, and mice inoculated with these spores died subsequently of tetanus. Kitasato was thus materially assisted in his isolation of the tetanus-bacilli by the fact that they form spores more rapidly than the other bacilli with which they are often associated, and these spores then successfully resist the high temperature which destroys the other micro-organisms. In the course of his experiments, Kitasato succeeded in procuring plate-colony-cultivations and in inducing tetanus in mice from their inoculation, and thus affording the rigid proof of the connection between this particular micro-organism and tetanus.

The spores of the tetanus-bacilli are very widely distributed, not only in garden soil, but in stables, hay-lofts, etc., and as they retain their vitality and their virulence for many months, even when dried and kept at the ordinary temperature of the air or buried in soil, they must be reckoned amongst the most determined and cruel of our microscopic foes.

Quite recently a most remarkable instance of their distribution has come under observation. A small child happened to cut its finger with an ordinary kitchen knife ; its father endeavoured to stop the bleeding of the wound by binding it up with some cobwebs, a superstitious practice which is more "honoured in the breach than the observance," for the child developed nearly a month later typical symptoms of tetanus. It was proved beyond doubt that the spider's web was responsible for the mischief, for rabbits and guinea-pigs inoculated with some web taken from the same place died under particularly well-defined symptoms of tetanus. Doubtless the spores had been caught in the web, conveyed thither by some chance current of air, and had remained contentedly attached until the opportunity came for them to exercise their disastrous powers.

It has also been long known that the poisoned arrows of the savage tribes produce symptoms of tetanus in their victims, and there can be no question that in the preparation of such arrows, dipping them as they do in the mud of certain swamps and allowing them to dry in the sun, the

natives unconsciously are availing themselves of the enduring and virulent properties of the tetanus-spores.

Another organism which has been very carefully studied, and whose character is yet the subject of speculation and much controversy, is the well-known comma-bacillus, identified by Koch as the responsible cause of Asiatic cholera. At present,

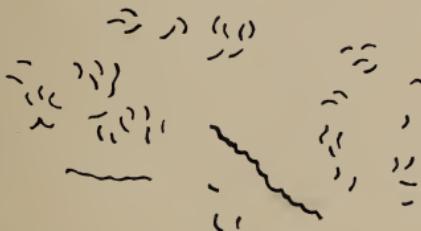

Fig. 39.—Spirilla of Asiatic Cholera, commonly known as Koch's Comma-bacilli. (*After Koch.*)

until some other agent has been brought forward which can be shown to possess a better claim for this distinction, we must be content to recognize Koch's organism as the exciting cause of cholera, resting its title as it does upon an immense mass of evidence and most careful experimental investigation.

In the accompanying figure is represented a microscopic preparation of the comma-bacilli or

spirilla, as they are called in consequence of the curved, corkscrew form which they frequently assume when growing in liquids.

The bacillus of typhoid fever affords another instance of a particular micro-organism being associated with a disease, but in which the difficulties of direct experimental evidence have not been overcome in such a manner as to present the same clenching proof as has been furnished in the

Fig. 40.—Bacillus of Typhoid Fever. (*After Migula.*)

case of the bacilli of tetanus or tuberculosis. The following figure shows the ordinary appearance of the so-called Eberth-Gaffky bacillus of typhoid fever. In a previous drawing it was represented, it will be remembered, surrounded with its flagella or organs of locomotion, which are only rendered visible by submitting the preparation to a special method of staining before microscopic examination.

But enough has been said to pave the way for the better appreciation of the marvellous manner

in which these investigations have led, and are still leading, to the most important results in medicine. Preventive medicine, which is essentially a product of the present century, has advanced with giant strides in consequence of the rapid growth of our knowledge concerning these microscopic foes and their habits. In this great advance we have in England unfortunately lagged behind. Signs are not wanting, however, that public opinion is slowly changing in its attitude towards this branch of science, and is beginning to appreciate the importance of such beneficent investigations.

VI.

THE THEORY AND PRACTICE OF PREVENTION IN DISEASE.

WHEN we come to inquire how it is that some of these minute organisms are capable of producing these disastrous effects upon the animals in which they grow and multiply, we find that the specific symptoms to which they give rise are not, in all probability, due to the mere presence of these living particles as such, but to the fact that they elaborate within the tissues of the body certain chemical substances of a highly poisonous nature, and that these poisons, and not the microbes themselves, are the real cause of the mischief. These poisonous chemical substances may be elaborated by microbes when growing in artificial cultures outside the body; thus, when meat and other albuminous substances begin to undergo decomposition, they are frequently pos-

sessed of most intensely poisonous properties. We are all of us familiar with those remarkable instances, of which we frequently read in the papers, of a whole family being poisoned by partaking of some particular dish of meat, fish, or the like. Now, such cases are nearly invariably due to the food in question having been in an unsound condition ; before being cooked, it has harboured certain micro-organisms which have produced these particular chemical substances, and whilst the microbes have been destroyed in the cooking, the poisonous character of these elaborated substances has remained unchanged by the process.

It is therefore to the absorption and circulation within the system of these intensely poisonous substances, elaborated by specific micro-organisms, that the particular disturbances of the animal system, which characterize these diseases, must be traced. The action of these pathogenic bacteria may, in fact, be compared, not to that of poisoning some one with, for instance, *nux vomica*, but it is as though the seeds of this poisonous plant could be introduced into the body of an animal, and there spring up into the plant itself, producing

its poisonous materials within the system of the animal. In fact, by introducing into an animal these organized poisons like tetanus or tuberculosis, we introduce not, strictly speaking, a poison at all, but a complete poison-manufactory, or a piece of machinery which will elaborate deadly poisons out of the animal tissues and juices on which the machine is thriving and extending its dimensions. This is no fanciful picture at all, for in several cases the actual poisons produced by these parasitic micro-organisms have been both discovered and isolated. Thus Brieger has described substances which he was able to obtain from pure cultivations of the typhoid and tetanus bacilli. In the case of the typhoid growth, he isolated a material which he called typhotoxine, whilst from the products elaborated by the tetanus bacilli he procured a substance—tetanine—which, when injected into animals, produces characteristic tetanic symptoms ; and tetanotoxine, likewise obtained from tetanus cultivations, in employing which he was able to induce some of the symptoms accompanying tetanus. Brieger has also isolated a very poisonous substance from decomposing

mussels, and other poisonous materials have been separated from putrefying cheese, etc.

But investigation has not been allowed to stop here; scientific men have not been content with merely unravelling the cause of these terrible phenomena which are constantly going on around us, but having carefully taken the measure, so to speak, of these countless hordes antagonistic to human life, reconnoitred their strongholds, and examined the weapons with which they fight, they have, without resting from their arduous labours, at once set about devising methods calculated to break and destroy the cruel power which these innumerable hosts have so long exercised, almost undisputedly, over defenceless mankind, and the animal kingdom in general.

There were, indeed, weighty reasons for pushing the inquiry in this direction, for the abundant experience of zymotic disease in the past gave strong indications of the kind of way in which possibly these diseases might some day be brought into subjection, and their destroying power curtailed. It has always been a familiar observation, that one attack of a zymotic disease generally

protects the individual from a second attack of the same disease, for although there are some persons unfortunate enough to suffer twice or even three times from measles or scarlet fever, still we all know that in by far the greater number of cases persons suffer but once from these and most other zymotic diseases. It is also a fact, with which physicians have long been familiar, that the intensity of these diseases is subject to great variations, not only in different persons, but also at different times and in different places. Thus sometimes scarlet fever or diphtheria will appear in a place as very serious diseases, with a large number of bad cases and many deaths, whilst at another time or in another place they may come in a much milder form, with few deaths and few serious cases. These remarkable phenomena early attracted great attention in the case of small-pox, in which the further extraordinary observation was made, that if the disease had been accidentally communicated by direct inoculation from one person to another, especially in childhood, the attack was generally a lighter one than usual, the person being protected against further attacks in

the future. This led to the custom of regularly inoculating with small-pox, which was much practised in the East, and was introduced into this country in the last century, and much resorted to until the epoch-making discovery of Jenner, in 1799, nearly 100 years ago, that persons might be similarly protected by being inoculated with *cow-pox*, a disease not unfrequently affecting the cow and the horse, but not naturally occurring in man. Inoculation with this disease, or *vaccination* as it is generally termed, had the advantage over the inoculation with small-pox, that it gave rise to an even still milder disease, and less dangerous than the mild form of small-pox which generally results from inoculation. This great discovery, made so many years ago, and which has so greatly mitigated the ravages of small-pox, is all but universally regarded as one of the greatest triumphs of Medicine, and indeed the foundation-stone of that department of Medicine which we now commonly call Preventive Medicine, and for which the immediate future extends hopes of still more majestic development than the past. This discovery of Jenner's, then, remained an isolated

achievement, until the careful study of micro-organisms and their effects, during the past fifteen years, threw fresh light upon these wonderful and hitherto puzzling phenomena.

The new ground in this direction was first broken by Pasteur, in the course of his investigation of a very fatal zymotic disease which affects poultry-yards, and which is known as Chicken-Cholera.

Pasteur found that if the artificial cultures of this

Fig. 41.—Bacillus of Chicken Cholera.

bacillus were preserved for a period of nine or ten months, they produced on inoculation into fowls only a trifling instead of the fatal malady, yet the birds were thereby permanently protected from subsequently contracting the disease. Moreover, on making fresh artificial cultures from this attenuated virus, they also were found to be only capable of setting up the milder form of the disease. Thus in this simple manner Pasteur succeeded in artifi-

cially cultivating a race of Chicken-cholera bacilli not only devoid of fatal properties, but able also to protect from subsequent inroads of the malignant bacilli. This discovery made in 1877 was a most material advance in the study of the great question of Preventive Inoculation, and although practically affecting only the welfare of the humble barn-door fowl, and the pocket of the poultry-farmer, was still an earnest of the triumphs over zymotic disease that were at hand.

The next disease to receive attention from this point of view was *Anthrax*, or *Woolsorters' disease*, which we have seen is so fatal, both to man and many of the lower animals, especially horned cattle, sheep, rabbits, guinea-pigs, and above all white mice.

The methods adopted for obtaining protection or immunity from Anthrax have been of the most varied and instructive character, and it will be well worth our while to investigate them more closely. In carrying on his studies upon Anthrax, Pasteur found that the virulence of the bacilli was greatly impaired by a temperature only very slightly in excess of blood-heat, and that if they were kept in

artificial cultures at a temperature of 42—43° C. for a period of 43 days, they were so much weakened as to be no longer fatal even to the most sensitive animals. Moreover, on starting fresh cultures from these weakened ones, the new cultures were found to preserve the character of the old ones, and were from the first of the same non-fatal kind ; animals inoculated with them suffer scarcely any indisposition, but are notwithstanding perfectly protected from Anthrax.

Pasteur did not delay in making this brilliant laboratory achievement available for practical application, and for nearly ten years past this attenuated virus has been prepared on a large scale under M. Pasteur's superintendence for distribution throughout the world. Pasteur's first great experiment with this attenuated virus outside the laboratory is particularly noteworthy. On the *5th of May, 1881*, there were brought to him twenty-four sheep, one goat, and six cows, all of them animals eminently susceptible to this disease. They were all inoculated on this day with Pasteur's attenuated virus, and twelve days later they were again inoculated with a rather less attenuated virus.

On May the 31st, all these inoculated animals, as well as twenty-four sheep, one goat, and four cattle not previously inoculated, received severally an injection with virulent anthrax. On June the 2nd, or three days later, twenty-one of the sheep and the goat which had not been inoculated were dead, two other sheep were dying, and the last one was also attacked later on in the day, *whilst not one of the previously inoculated animals was affected.* It is difficult for any one not engaged in scientific pursuits to fully realize how the triumph of that moment must have rewarded the years of patient and religious labour of the Seeker after Truth. The extent to which this protective treatment has been taken advantage of may be gathered from the following figures recently communicated by M. Pasteur to Sir Joseph Lister—

Two and a half million sheep, 320,000 horned cattle, 2,861 horses, have been inoculated from the Institut Pasteur, whilst in 1888-9 material was also sent to India for the inoculation of 1000 elephants.

Within the last few years great attention has been bestowed on the chemical substances which

these disease-producing organisms generate, and numerous investigators have succeeded in calling forth many of the symptoms of a disease by injecting the products of these organisms from which the organisms themselves had been carefully removed. But not only has it been found that these products free from organisms are capable of inducing the symptoms of a disease, but the animal so experimented on is often thereby protected from the disease itself. This method of securing immunity by means of bacterial poisons has been most beautifully worked out for anthrax by Mr. Hankin of Cambridge. Mr. Hankin has succeeded in isolating from anthrax-cultures a substance which has many points of similarity to snake-poison; he calls it the *Toxalbumose of Anthrax*, and he finds that this substance is so poisonous that if he injects into a rabbit a dose of not more than $\frac{1}{5000000}$ of its body-weight the animal is killed, whilst if he takes only half that amount, or $\frac{1}{10000000}$ of its body-weight, the animal does not die, but on the contrary is thereby protected against anthrax. Indeed, by carefully proportioning the dose of this toxalbumose, Hankin has actually succeeded in protecting

white mice, which are the most susceptible of all animals to anthrax.

The most obvious explanation of these remarkable results would appear to be that the introduction of a suitable quantity of this poison into the animal system accustoms the animal to the action of the poison, and prepares the animal to successfully withstand the larger quantities of this poison which are generated within it when the virulent anthrax bacilli are subsequently inoculated. We are all of us familiar with the fact that the system can by practice be made to tolerate considerable doses of powerful poisons ; thus the habitual smoker can endure without inconvenience doses of nicotine, the poisonous principle of the tobacco-leaf, which would make a sorry sight of the inexperienced novice to the fragrant weed ! The curious point of difference between the two phenomena is, that in the case of anthrax the animal becomes habituated to the poison by a single injection, whilst the tolerance of tobacco is only acquired after a prolonged apprenticeship ; it is in fact as though the first cigarette should prepare a man to forthwith venture upon a full-flavoured

cigar, a proceeding the effects of which it is unnecessary to say would stamp themselves upon the memory for the remainder of his life.

Something similar to Hankin's results had been previously observed in the case of snake-poison, for it had been found that by injecting very minute doses of the essential principle of this poison into pigeons, they acquire the power of withstanding no less than seven times the ordinary deadly dose of snake-poison, even if administered three months afterwards.

But of all communicable diseases there is probably none which inspires such absolute terror and consternation as Hydrophobia or Rabies, and although the disease is fortunately so rare that comparatively few persons have actually seen a human being suffering from it, still the terrible nature of the disease is so well known that the dread of it is shared by all.

It was doubtless the appalling character of this disease and the helplessness of physicians to cope with its attacks that first led Pasteur to turn his great mind to its investigation now eleven years ago. Peculiar difficulties have surrounded the study

of this disease, for in spite of the most careful and long-continued attention that has been given to it by some of the best observers of the day, all have hitherto failed in discovering the exciting cause, although of course no doubt can exist, from the manner in which it is communicated, that it must be due to an organized poison, more or less similar in character to those which we have already been considering. But although even Pasteur's eagle eye was unable to discover the exciting cause of hydrophobia, he was, by the scientific use of the imagination, and by ingenious experiments, successful not only in devising a method for protecting the individual against the virus of hydrophobia, but actually in warding off the attack of this disease by means of a treatment which is only put into operation after the infection has taken place. This marvellous discovery, which is assuredly one of the grandest achievements of scientific intuition and deductive acumen, it is which has made M. Pasteur's laboratory in Paris the Mecca for anxious pilgrims coming from the east and the west, from the north and the south, speaking a Babel of languages, some clothed in rags and some in soft raiment, but all

possessing one thing at least in common—the gnawing care of having been bitten by a mad dog, cat, jackal, or rabid animal of one kind or another. Such, indeed, was the gathering which in 1886 I myself witnessed in the small building hastily extemporized for M. Pasteur's purposes, and which has since been replaced by the palatial Institute erected by the joint efforts of a grateful community and of a prudent Republican Government to afford a wider arena for the commanding genius of Pasteur.

We will now endeavour to make ourselves acquainted with the leading features of this preventive treatment of Rabies, the report of which has reached to the uttermost parts of the earth.

The starting-point of Pasteur's experiments on Hydrophobia was a child suffering from this disease, as the result of being bitten by a mad dog. He took some of this child's saliva and inoculated it under the skin of a rabbit. The rabbit was dead in two days ; and on inoculating the blood of this first rabbit into a second, the latter was also found dead in two days. This rapid course of the disease is so unusual in hydrophobia that it

appeared very doubtful as to whether he was really dealing with this disease, and not some other form of infection.

In subsequent experiments Pasteur invariably adopted the plan of inoculating with the brain of the affected animal into the brain of a healthy one, as in this manner the disease was produced with most certainty, and of the most uniform character, as long as the same kind of animal was employed. Pasteur was now guided by his experience gained in dealing with anthrax, and in which he had observed that the virulence of the disease would be modified by passing from one species of animal to another. Inoculating from hydrophobic dogs into rabbits, he found that the virulence of the disease was greatly intensified, death following much more rapidly after inoculation than in the rabies of dogs. On the other hand, by inoculating from dogs into monkeys, he found that the virulence of the disease became diminished, and after being transmitted several times from monkey to monkey, the malady ceases to be fatal. It was thus possible to obtain virus in all degrees of malignity—*virus of great strength from the rabbit, of medium strength*

from the dog, and of low strength from the ape. Pasteur now endeavoured to accustom an animal to the rabies-poison by treating it successively with poison of increasing strength; this was done by preparing a series of rabbits which were to yield the poison of different degrees of virulence. The first rabbit was inoculated with the weakened virus from a monkey, from this rabbit the disease was communicated to a second, from that to a third, and so on in series, the intensity of the virus increasing as it passed from one rabbit to another.

With this graduated scale of poisons he now attempted the protection of dogs. Twenty dogs were each successively inoculated with the graduated rabbit-poison, beginning with the weakest, and giving a stronger poison at each successive inoculation. After these twenty dogs had undergone this treatment, they were each exposed to infection with virulent hydrophobia, the result being that three-fourths were found to resist the infection, which was so eminently satisfactory that it stimulated Pasteur to further perfect the process. He now found that the graduated scale of hydrophobia-poison could be obtained in a more simple

manner than that which I have described, for he observed that by keeping the spinal marrow of a rabbit which had died of rabies in a dry atmosphere its virulence became weakened from day to day, and after about fifteen days the virulence had almost completely disappeared. In this way a graduated series of poisons can be obtained by having a series of spinal cords, the strongest being one day old and the weakest fifteen days old. With such a series of poisons, obtained in this extremely simple manner, Pasteur now commenced the treatment of fifty dogs. Each dog was submitted to a treatment extending over ten days, during which period it received a number of successive inoculations with the rabbit-marrows of different ages, beginning with the oldest and therefore weakest virus, and ending with the youngest and strongest virus. On subsequently exposing these fifty dogs to infection with virulent hydrophobia, they were found to be all protected, and this protection proved to be permanent for at least two years.

With such results obtained in the laboratory, Pasteur now felt justified in extending the treat-

ment to human beings. The first case treated was that of a child bitten on July 4th, 1885, since which a long string of patients have passed through the process, both at the Institut Pasteur and the other places where arrangements have been made for bestowing upon suffering humanity the fruits of this latest departure of scientific research. Such institutions have been established in Russia, Hungary, Italy, Sicily, Brazil, Mexico, Turkey, the United States, and Roumania, and in Great Britain we are at length also in possession of an Institute of Preventive Medicine, although for years previously we have had to have recourse in our need to foreign places of the kind.

At the Institut Pasteur the following numbers have been treated—

Year.	Number Treated.	Number Died.	Percentage.
1886	2,671	25	.94
1887	1,770	13	.73
1888	1,622	9	.55
1889	1,830	6	.33
1890	1,540	5	.32

The mortality amongst persons bitten by rabid dogs and not submitted to treatment may be taken at 15—20 *per cent.*

The chance of escape is mainly dependent upon

two circumstances, of which the *first* is the time which has elapsed between the infliction of the wound and the commencement of the treatment; if the patient die within fifteen days after the completion of the inoculations, it is considered that the case was from the first a hopeless one, as it shows that the disease had already commenced its activity during the treatment, and such cases are not recorded in these statistics; and *secondly*, the gravity and position of the wound are of much importance in determining the chance of successful treatment. Thus in the case of the patients treated in 1890, the mortality for

Bites on the Head was	'85 per cent.
" " Hands was	'45 "
" " Limbs and body was		'00	"

Again, bites by mad wolves are far more dangerous than those by mad dogs, as the virulence of the disease is greater in the wolf than in the dog.

In the following table I have recorded the most recent method of treatment which has been pursued at the Russian Military Station at Tiflis during the year 1890. The patient is subjected to two distinct series of inoculations; the first extending

over nine days, stronger and stronger virus being employed from day to day; whilst in the second series, which extends over ten further days, a return is made to weak virus, which is then again strengthened from day to day as indicated in the table—

<i>I. Series.</i>			<i>II. Series.</i>

It is only natural that scientific thinkers should have endeavoured to systematize the vast mass of accumulated facts concerning the relationship between the animal system and these various micro-organisms which have the power of living parasitically upon it, and causing it so much mischief. Numerous theories have indeed been

propounded to account on the one hand for the injuries which these organisms are capable of doing the body, and on the other hand of the power which the body possesses of warding off their attacks. The construction of a single theory harmonizing with all the observed facts in this matter is attended with the greatest difficulties, nor have these difficulties been yet overcome, as we are still without any working hypothesis which gives a satisfactory explanation of *all* the phenomena to which I have referred.

This would obviously not be a suitable place to balance the arguments for and against the various theories which have been suggested in explanation of these matters ; but there is one theory, which on account of its extreme ingenuity and the large amount of experimental evidence which has been marshalled in its support by its originator, I cannot refrain from referring to. In studying these communicable diseases it becomes obvious even to a superficial observer that a species of contest or warfare takes place between the micro-organisms of these diseases and the body of the animal they infest. In some cases the micro-organisms, and in

other cases the body is victorious ; in some again the battle is long, in others it is short. In the case of animals highly susceptible to a disease, the victory almost invariably lies with the microbes, whilst in the case of those which enjoy a natural immunity, or in which immunity has been artificially conferred by means of one of the methods of

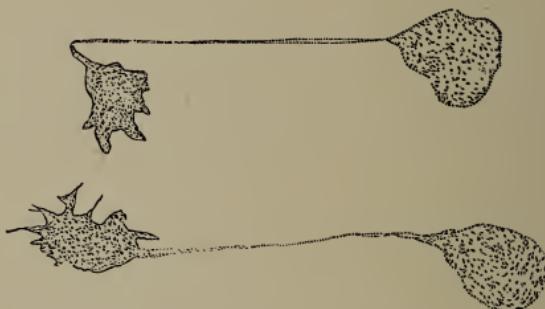

Fig. 42.—“A common or pale colourless corpuscle is shown after it has separated into two lumps, connected by a thin bridge. The lower of the two figures is a later stage of movement of the one above.”—*Atlas of Histology*, by E. Klein and E. Noble Smith.

protective treatment which I have mentioned, the victory is secured by the body.

M. Metchnikoff, an illustrious Russian bacteriologist, conceives of this struggle on behalf of the body being carried on by certain small living cells or corpuscles which are present in the blood and some of the other fluids which bathe the tissues of the living body. The cells to which is entrusted

this warfare include the ordinary colourless corpuscles and other cells, to all of which the collective name of *Leucocytes* has been given (see Fig. 42). These leucocytes are endowed with an individuality of their own, having the power of independent locomotion, which they accomplish by what is known as amoeboid movements.

In the accompanying figure such a leucocyte is represented executing one of these remarkable movements.

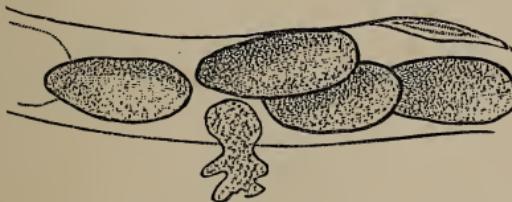

Fig. 43.—Leucocyte commencing to traverse the wall of a capillary. (After Metchnikoff.)

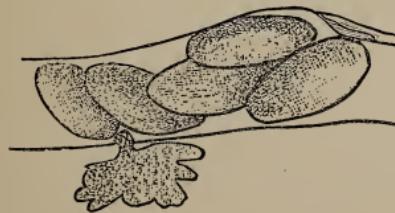

Fig. 44.—The same leucocyte as in Fig. 43, at a later stage. (After Metchnikoff.)

In the first of these figures a leucocyte of irregular contour is represented as commencing to traverse

the wall of a blood-vessel, the latter being filled with oval blood-corpuscles. The second figure represents the same leucocyte after a short interval of time, thus exhibiting the amoeboid movements by means of which these bodies propel themselves.

It has long been known that if fine solid material is injected into the blood, these solid particles become surrounded by such leucocytes, and if of a digestible nature they become assimilated by the leucocyte, but if unsuited for digestion these particles are ejected as shown in the next figure.

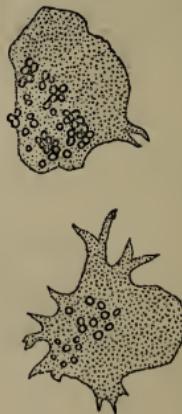

Fig. 45.—Leucocytes containing particles of vermillion. The lower figure represents the same leucocyte after it has got rid of some of its load. (*After Klein and Noble Smith.*)

There is, thus, no question that these leucocytes act as the scavengers of the blood, but Metchnikoff

conceives of them as not only performing these menial duties, but also endowed with a martial spirit which is called into activity when the body is threatened with an invasion by the bacterial hordes. As soon as these enemies of the body effect an entrance at any point, the leucocytes, according to M. Metchnikoff, muster in large numbers, and close in deadly contest with the invaders. In this struggle the leucocytes avail themselves of their voracious appetite, and enclose within their capacious bodies great numbers of their lilliputian foes, whilst the latter employ as their engines of war the deadly poisons which we have seen they are capable of manufacturing with such rapidity and skill.

Nor must it be supposed that this picture is a mere romantic flight of fancy on the part of the imaginative Russian savant; on the contrary, his theory is based on the most careful observations and experiments made by himself and others.

In elaborating his theory of Phagocytosis, as this particular behaviour of certain cells present in the tissues and blood-vessels of the body is called, Metchnikoff has not restricted his study to their

behaviour in the higher vertebrata, including man himself, but has gone back to the most rudimentary forms of life in the animal kingdom, commencing with the unicellular organisms, or protozoa in which the nervous and vascular systems are entirely absent.

In thus commencing with the simplest and working up to the most complex organisms, tracing the development of particular pathological processes from their beginning to their consummation, Metchnikoff has simply followed the path dictated by the principles of evolution, and has with marvellous skill and ingenuity pursued and marked out the intricate progress of these phenomena from species to species. Thus in his own words:¹ “Il n'est point nécessaire de fournir de preuves spéciales pour affirmer que la maladie et les processus pathologiques ont leur évolution comme l'homme et les animaux supérieurs eux-mêmes. Chez tous les organismes, à partir des êtres les plus inférieurs, nous trouvons déjà des maladies infectieuses produites par des parasites appartenant

¹ “Leçons sur la pathologie comparée de l’Inflammation,” par Élie Metchnikoff. Paris, 1892.

à des groupes différents. Il est donc tout naturel de supposer que ce parasitisme occasionne une série déterminée de troubles dans l'organisme infecté et provoque aussi des phénomènes réactionnels de la part de ce dernier."

Now although from what has been said these leucocytes would appear to have a voracious appetite, inasmuch as they will engulf such unremunerative materials as particles of vermillion, yet in reality their tastes are by no means so catholic as might be imagined. They are, on the contrary, endowed with a highly discriminating palate, and this discrimination not only renders them capable of exercising a most refined selection in what they will engulf, but determines their movements also. Thus if the mesentery of a frog be moistened with a solution of quinine, the leucocytes remain quietly in the interior of the blood-vessels, in spite of the dilated condition of their walls affording them the most favourable opportunity for migration. It was at first supposed that this inaction on the part of the leucocytes was due to the quinine having paralyzed them, inasmuch as it acts deleteriously on the protoplasm of

the tissues, but on repeating the experiment whilst confirming their negative behaviour under these circumstances, the surprising fact was revealed that on removing such leucocytes from the blood-vessels, their inherent motility had been in no way impaired, their amœboid movements being as characteristic as ever. Now this showed in the most striking manner that their previous immobility was due to a deliberate determination on the part of these leucocytes to have nothing whatever to do with the particles of quinine, and also that this decision had been arrived at in consequence of information of some sort or other which had penetrated to them when shut up within the walls of the blood-vessels. This gift of apparent discrimination and marked individuality of action which leads them to be attracted by some substances and repelled by others is now generally known as *Chimiotaxis*.

In the case of micro-organisms this chimiotaxis is exhibited in a most remarkable manner. Some varieties are absorbed by the leucocytes and others are refused, and refused moreover in some cases where their destruction by the leucocytes is of the

most vital importance to the organism to which the leucocyte belongs. This seemingly unaccountable behaviour of the leucocyte has been attributed to the chemical products elaborated by different bacteria within the animal on which they are parasitic, the substances produced by some causing attraction, those produced by others causing repulsion of the leucocytes.

In many of the most virulent and fatal types of disease, such as chicken-cholera, the leucocytes stand aside altogether, and refuse to have anything to do with the microbes. This fact may possibly account for the great mortality which we have seen occurs amongst fowls infected with this chicken-cholera, and here in the absence of the necessary powers to throw off the disease in the animal itself, man has had to interpose with artificial expedients, enabling the animal to successfully combat with its most unwelcome parasite. But this negative behaviour of the leucocytes in such cases in which their action would be of primary importance to the animal affected, has naturally afforded a favourable opportunity for the opponents of M. Metchnikoff to attack his leucocytic-theory.

But the ingenious Russian is not easily defeated, and he again shelters himself under the mantle of evolution. He urges that just because the development of the powers of the phagocytes takes place in accordance with the laws of natural selection, and not in pursuance of any one predetermined path, we find instances where, in consequence either of their functional activity being suspended or being prejudicially exercised, the well-being of the organism is not only gravely menaced, but death itself frequently ensues. This all takes place, says M. Metchnikoff, because the functions of the phagocytes are not yet perfected, because their development is still going on, and it is this gradual evolution of their powers which has rendered possible the intervention of human skill in assisting the organism to perform what it is not yet capable of accomplishing by itself.

This theory of Phagocytosis is so interesting and important, and opens up such a wide field for speculation and research, that I must be pardoned for having dealt with it in more detail than perhaps the compass of this little work would warrant. In conclusion, I will endeavour to show in the follow-

ing figures the nature of the struggle which is supposed to take place between certain bacteria and the leucocytes.

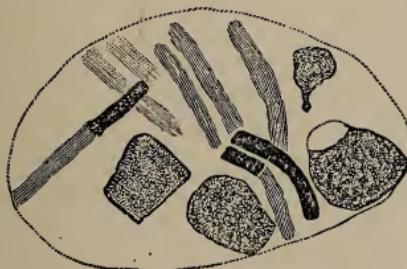

Fig. 46.—Leucocyte of White Rat, enclosing Anthrax bacilli. (*After Metchnikoff.*)

In this figure (Fig. 46) a large oval cell or leucocyte is represented as having engulfed a number of rod-like bodies, the bacilli of anthrax, which are undergoing gradual degeneration and decay within; thus those bacilli which are still possessed of

Fig. 47.—Leucocyte of Monkey, enclosing spirilla of recurrent fever. (*After Soudakewitsch.*)

vitality are of their normal size and sharply defined, whilst those which have suffered partial resolution are swollen up, and but faintly marked.

In Fig. 47 the large irregular cell or leucocyte is represented enclosing a number of the coiled spirilla of recurrent fever, whilst in the following figure (Fig. 48) the mortification and decay of one of these spirilla is exhibited through its becoming uncoiled and disjointed.

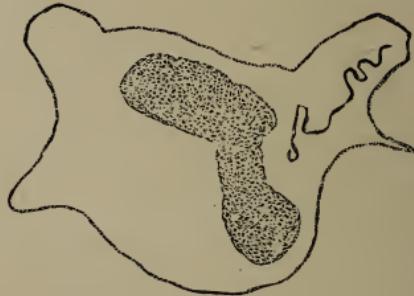

Fig. 48.—Leucocyte of Monkey, containing spirillum of recurrent fever, showing the disintegration of the latter. (*After Soudakewitsch.*)

In this contest between the leucocytes and the bacteria, according to Metchnikoff, if the leucocytes are defeated, the animal falls a victim to the disease, whilst if the leucocytes are victorious and the bacteria exterminated, the animal recovers, and the severity of the disease will depend upon the severity of the struggle between the combatants.

Moreover, if the leucocytes have been once successful in such a contest with a particular species of bacteria, they will on a future occasion secure the victory over the same species with far greater ease ; and on this account one attack of an infectious disease commonly protects, as we have seen, either temporarily or permanently, against a second attack of the same disease. Also, if the bacteria are introduced in a weakened or attenuated condition, the leucocytes naturally have an easy task in subduing them, yet by the experience gained in this trivial contest they are often able to successfully oppose the inroads of the most virulent forms of the same species. This is in fact the manner in which the upholders of Metchnikoff's theory account for the phenomenon of immunity acquired by protective inoculation. Indeed it has been shown by actual experiment that if the bacteria are defended from the attacks of the leucocytes, they can actually multiply abundantly in the blood of the immune animal. Thus, if the spores of virulent anthrax are enclosed in a little paper packet, and this is introduced under the skin of a rabbit which has been rendered immune towards anthrax, the spores

germinate inside the paper envelope, and multiply abundantly therein, but any of the anthrax bacilli getting outside the envelope immediately fall into the clutches of the leucocytes and are destroyed.

But we have seen that immunity may also be secured by protective inoculation, not with weakened or attenuated bacteria, but with the chemical products elaborated by the particular bacteria. This method of obtaining immunity is supposed to depend upon the leucocytes becoming thereby accustomed to the particular bacterial poisons in small doses, and thus being enabled to cope more easily with the generators of these same poisons when they are introduced in person into the body of the animal.

It is, however, very difficult to harmonize with this theory some exceedingly remarkable and interesting observations recently made by Kitasato, to whom reference has already been made. Kitasato in the course of his investigations on the phenomena connected with tetanus or lockjaw, found that it is possible to secure immunity from this disease by injecting into rabbits a small quantity of a chemical substance known as Tri-

chloride of Iodine. This discovery is remarkable enough in itself, but still more wonderful is that which followed, viz. that on injecting only a few drops of the blood of this protected rabbit into a mouse, the latter also became protected against tetanus. And further, he found that mice already infected with tetanus, and in which the tetanic symptoms had already commenced in several of the extremities, could still be rescued by having recourse to an injection with the blood of rabbits which had been protected against tetanus with the trichloride of iodine.

This remarkable action appears to be due to the extraordinary power possessed by this protected rabbits' blood of destroying the particular poison generated by the tetanus organism, and this destructive power can actually be demonstrated outside the animal body altogether in the most conclusive manner.

Thus Kitasato took an artificial culture of the tetanus bacilli, which had been growing for ten days. This culture-liquid he passed through a filter to remove the bacilli, and the clear liquid so obtained is of the most intensely poisonous

character, for ($\frac{1}{20000}$ c.c. or) $\frac{1}{1000}$ of a drop is sufficient to kill a mouse in 4—6 days. (One c.c. or) twenty drops of this poisonous liquid were mixed with 5 c.c. of the blood-serum of a protected rabbit, and after twenty-four hours a quantity of this mixture (containing 300 times the fatal dose) was inoculated into each of four mice, but not one of them was affected, thus clearly showing that the tetanic poison had been destroyed by the twenty-four hours' contact with the rabbit's blood-serum.

These results are so striking that they require but little comment; it is obvious, however, that they reveal to us the possibility of combating disease with entirely new agents, and who can say to what achievements the path thus inaugurated by Kitasato may not lead in the future?

The youthful science of Bacteriology is indeed full of surprises, and every year bears witness to the astounding strides with which it grows, whilst day by day it is being more widely recognized of what stupendous importance to man is the message which it has to deliver.

During the earlier childhood and adolescence of

this new science, it was generally believed that this message was of a gloomy character, and one which it would be better to leave untold, for to the public it seemed as though it had nothing but death and destruction to reveal as lurking where danger was hitherto unsuspected. For many years Bacteriologists had apparently nothing to announce but the discovery of new and subtle enemies to mankind, and to produce poisons possessing such a degree of malignity that beside them the venom of snakes and the most potent drugs of the apothecary appeared as comparatively harmless or even friendly. In reality, however, these deadly foes and poisons have always existed before, and have wrought their lethal work in the dark until exposed and branded by men of science, who after years of patient labour are now teaching the world how these foes may be vanquished, and how these old but until recently undiscovered poisons may be counteracted and rendered innocuous by the administration of New Antidotes.

VII.

THE ACTION OF LIGHT ON MICRO-ORGANISMS.

KNOWING as we now do that micro-organisms, invested with such wide and various powers for good and evil, are intimately connected with vital processes, both animal and vegetable, and that they are inseparably associated with all our surroundings, the question naturally arises, what circumstances tend to keep them in check, or what are the conditions in the struggle for existence with which they have to contend?

That the members of this diminutive though powerful commonwealth are kept within certain bounds is obvious, otherwise they would be present in numbers entirely baffling our powers of expression. We know that some micro-organisms at least are capable of starting a new progeny in considerably less than an hour; if we care to work out theoretically the microbial population

which may arise under favourable circumstances in the course of forty-eight hours from one parent bacillus, we shall arrive at the following remarkable figures :—

THEORETICAL MULTIPLICATION OF BACTERIA.

Hours.						Number of Bacteria.
0	1
1	2
2	4
3	8
4	16
5	32
6	64
12	4,000
24	16,000,000
48	280,000,000,000,000

On contemplating such a result, perhaps the first deterring agent which occurs to us will be the limited supply, even for microbial needs, of food material available for such a population. This is undoubtedly an important factor, but added to it are many others, such as unfavourable external conditions, of heat or cold, of moisture or dryness, uncongenial material environment, etc., and last but not least, the action of Light.

That sunshine is able to destroy micro-organisms was first discovered about sixteen years ago, and it is not a little gratifying to recall that the first and most important step in revealing the cleansing and disinfecting properties of sunlight was made in this country.

It was in the year 1877 that Messrs. Downes and Blunt read a paper ("Researches on the Effect of Light upon Bacteria and other Organisms") before the Royal Society, in which they described the investigations they had made on this novel and most interesting subject.

In these experiments sterilized Pasteur solutions¹ were placed in test-tubes, and were subsequently infected by introducing a minute quantity of a liquid swarming with bacteria, or by exposing the tubes for a short time to the air. These infected test-tubes were placed near a window with a south-east aspect, and left there for days, weeks, and even months. As a control, some of these tubes were carefully covered up in lead-paper in order to expose them to the same conditions as

¹ 100 parts of water, 10 parts candy sugar, 1 part ammonium tartrate, and the ash of 1 part of yeast.

the others, the light only being excluded. If the solutions became turbid it was concluded that the organisms had grown, whilst if they remained clear it was presumed no growth had taken place, but microscopical examination was also frequently resorted to, in order to determine this point more certainly. As a result of their observations, they stated that, under favourable conditions, exposure to light entirely prevented the development of these bacteria, whilst under less favourable conditions their growth was only thereby retarded. They found that whilst diffused light had certainly a damaging effect upon bacteria, the direct rays of the sun had a much more prejudicial influence.

In this way was demonstrated for the first time a perfectly new and most important property of the sun's rays, viz. the power of destroying that bacterial life which plays such a leading part, both for good and evil, in the economy of Nature. Downes and Blunt extended these initial observations in a very instructive manner by making experiments by which they ascertained that the destructive effect of the sun's rays is greatly

intensified if not entirely dependent on the presence of oxygen.

More precise results in this direction have been recently obtained by M. Momont in the Pasteur Institute. Instead of using mixtures of micro-organisms, Momont confined his attention to the behaviour of the anthrax bacillus and its spores under various circumstances when exposed to light. In the majority of his experiments *sporeless* bacilli were employed, obtained either from the blood of a rabbit dead of anthrax, or bacilli artificially deprived of their power of producing spores, and known as *asporogène* anthrax.¹ Momont found that when these bacilli were exposed to sunshine in broth, in the *presence* of air, they were killed in from two to two and a half hours, whilst in the *absence* of air they were still alive after fifty hours of sunshine. These results show very strikingly that the agency of

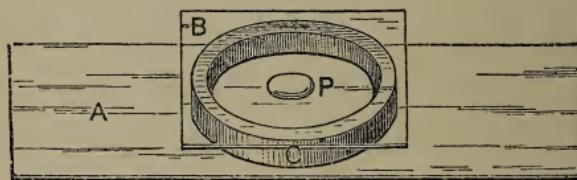

¹ Chamberlain and Roux made the interesting discovery that anthrax bacilli were unable to produce spores in bouillon to which a small amount of phenol had been added. Such sporeless bacilli are quite as virulent as ordinary anthrax bacilli.

light is immensely increased when acting in combination with air.

Momont also showed that the nature of the medium in which the organisms are suspended when subjected to light is of importance, a fact suggested by many previous observers. This point was worked out by Momont very carefully in the case of blood and broth respectively, and he found that in dried blood exposed to diffused light in the presence of air, anthrax bacilli were able to exist for seventy days, but when submitted to similar treatment in dried broth they died after twenty-one days. When placed in the full sunshine, however, the dried broth cultures were destroyed in from five to five and a half hours, whilst in dried blood, although their existence was somewhat prolonged, they yet succumbed in eight hours. Very different was the behaviour of the hardy spore forms, for when dried and exposed to sunshine, whether in the presence or absence of air, for one hundred hours, they were not destroyed.

Dr. Pansini has made some pretty experiments, in which he gives us more exact information as to the *rapidity* with which anthrax bacteria are

destroyed in sunshine. For this purpose he prepared what are known as drop-cultures of the particular organisms he was investigating. These drop-cultures consist in placing a drop of liquid containing bacteria on a thin slip of glass or cover-glass; the latter is then placed, with the drop on the under surface, over an excavated glass slide, or on the top of a glass ring cemented on to the slide, as seen in the following figure—

A, glass slide; B, cover-glass; C, glass ring forming the wall of the chamber; P, drop of nutritive liquid in which the micro-organisms grow. (*Klein.*)

Side view of above.

FIG. 49.—Suspended Drop-cultures.

In this manner the bacteria contained in the drop can be watched in a *living* condition under the microscope from hour to hour, or day to day. Now, Pansini prepared in this manner a series of drop-

cultures from a young cultivation of anthrax,¹ and after they had been in the sunshine for from ten to seventy minutes, the cover-glass was carefully removed and placed in melted gelatine, and after thorough agitation in order to insure the equal distribution of the organisms as well as their entire removal from the surface of the cover-glass, plates (*see* Frontispiece) were poured in the usual manner, and the resulting colonies counted. From the cover-glass kept in the dark, 2520 colonies of anthrax were obtained, whilst the following were derived from the cover-glasses which had been placed for different lengths of time in the sunshine:—

Cover-glass exposed 10 minutes to the sun, 360 colonies.

”	”	20	”	”	130	”
”	”	30	”	”	4	”
”	”	40	”	”	3	”
”	”	50	”	”	4	”
”	”	60	”	”	5	”
”	”	70 and more	”	”	0	”

Thus the destruction is rapid in the first period of exposure, but the more resistant of the microbes take a considerably longer time to annihilate,

¹ As no special precautions were taken to exclude spores, there is no guarantee that they were not present.

showing the individual peculiarities inherent in members of one and the same cultivation.

These experiments serve to illustrate a few of the complicating factors which surround the study of the bactericidal action of the sun's rays. In endeavouring to understand more fully this action, it was only natural that the different coloured rays composing the sun's beams should have been separately tested as regards their power of destroying bacteria. This point was also attacked by Downes and Blunt, but has been perhaps first most successfully dealt with by Dr. Geisler of St. Petersburg. This investigator decomposed the sun's light by means of the prism, and then exposed typhoid bacilli to the various parts of the spectrum, the gelatine tubes in which they were contained being so arranged that only particular rays fell upon them. The exposure was continued for two hours and a half, and it was found that the typhoid bacilli grew best in the red rays; in fact, no difference could be detected between their growth in these rays and in the dark cupboard. The development became more and more scanty in passing from the red to the yellow, green, and

violet rays, whilst the least growth of all was observed in the ultra violet rays.

The rays, therefore, which exert this destructive or inhibiting effect on bacterial life are precisely those which exert the most powerful action on the photographic plate. Of much interest also is the comparison which was instituted by Geisler between the potency of the sun and of the electric light in destroying bacterial life. Thus, whilst from two to three hours' sunshine was sufficient to produce a most markedly deleterious effect on the typhoid bacillus, it required over six hours' exposure to the full glare of a 1000-candle electric arc lamp, at a distance of only 39 inches, to produce a similar result. The great inferiority of this most dazzling of artificial lights when traversing only 39 inches is very clearly shown, when compared with the power exercised by the rays that emanate from the solar disc after traversing 93,000,000 miles of space!

Even if the exposure to the solar rays is not sufficient to actually destroy the bacteria, it may yet profoundly modify their character, and bring about the most important changes in their sub-

sequent behaviour. We have already learnt that a number of bacteria have the property of producing the most wonderful colouring matters; and one of these so-called pigment-producing bacteria has been made the subject of some very interesting experiments by a French investigator, M. Laurent.

The particular organism which he selected for his inquiries as regards the action of sunshine, is the so-called *Bacille rouge de Kiel*, a microbe originally obtained from water, and which owes its name to the beautiful red pigment which it produces when grown on potatoes, etc. In fact, in this and other respects, it is difficult to distinguish it from the familiar *Bacillus prodigiosus* (see p. 57), which, as we know, produces a magnificent patch of blood-red colour when inoculated on to a slice of potato.

If the slice of potato on which this *Bacille rouge de Kiel* has been streaked is exposed for five hours to the rays of a July sun, no growth whatever subsequently makes its appearance, the bacilli having been entirely destroyed by the sunshine. However, if the exposure to the sun is allowed to extend only over three hours, then the bacilli are

not destroyed, for a growth appears on the potato, but instead of this being brilliant red it is quite colourless, with perhaps a few specks of pale pink here and there; if only one hour's exposure is permitted, there is still a great deal of white in the growth, but there are more pink spots visible than are seen on the slice isolated for three hours. Now M. Laurent found that if he transplanted a little of this colourless growth on to a fresh slice of potato, the growth obtained on this potato was again colourless, whilst when taken from the colourless colonies on the slice exposed only for one hour, the growth was pink, showing that the shorter period of isolation had not sufficed to permanently produce a colourless race of bacilli. On the other hand, three hours' sunshine had so far modified the physiological character of this bacillus that as many as thirty-two successive colourless generations were obtained on slices of potato. Curiously enough, this loss of pigment-producing power, originally brought about by the sunshine, was only maintained as long as the slices of potato after being streaked with the growth were kept at a temperature of from 25—35° C.; if they were

preserved at from 10—25° C. the colour reappeared.

An exposure for three, four, or six hours to the sun in September and October was also found capable of modifying the pigment-producing powers of this bacillus, although M. Laurent warns us that the colour was not so uniformly removed, and a tendency to return to its original colour was noticeable. The presence of pink colonies amongst the colourless centres M. Laurent attributes to inequalities in the power of resistance possessed by individual bacilli, as well as to the uneven thickness of the growth in different parts of the slice of potato.

Still more recently MM. d'Arsonval and Charrin have examined the action of sunshine on the pigment-producing power of the *Bacillus pyocyaneus*, an organism frequently present in pus, and capable of producing a beautiful fluorescent green colour when grown in culture media. These investigators found that an exposure of from three to six hours to sunshine entirely deprived it of its powers of elaborating this green colour, only colourless growths making their appearance; whilst

when prolonged beyond this period the bacilli were completely destroyed. If, however, only the red rays of the spectrum were allowed to fall on the bacilli, even six hours' exposure could not impede the production of the typical fluorescent green colour ; and, indeed, when the period of exposure to the red rays was considerably extended, instead of being destroyed, they not only remained alive, but produced their pigment as usual, the red rays having put them to no sort of inconvenience.

But this loss of pigment-producing power is not the only modification in the physiological character of micro-organisms which exposure to sunshine is able to bring about. Of still greater interest and importance is the impression left by insolation on the disease-producing powers of virulent or pathogenic bacteria. In this connection comparatively little has so far been done ; but a most interesting contribution to this branch of the subject has been made quite recently by Dr. Palermo of Naples. It is true that as far back as the year 1885, M. Arloing stated that he had, by suitable exposure to sunshine, been able to produce weakened cultures of the anthrax bacillus,

which was thus deprived of a considerable portion of its virulence, and that in fact after about thirty hours' insolation, such anthrax cultures were converted into a sort of vaccine ; for guinea-pigs inoculated with them not only remained alive, but acquired a more or less pronounced degree of immunity towards subsequent infection with anthrax. This was, however, an isolated observation, and whilst in some cases it has been confirmed, in others it has been contradicted by later investigators.

Dr. Palermo, in his researches with Koch's cholera bacillus, specially undertaken to determine the effect of sunshine on the virulence of this organism, has made a most important contribution to this subject. These bacilli, besides being almost universally accredited with the honour of producing Asiatic cholera in man, are also fatal to guinea-pigs in about eighteen hours, whilst M. Sobolotny has just discovered that marmots also are especially sensitive to their action, a small quantity when introduced under the skin of these animals destroying them in a few hours.

Virulent cholera bacilli were exposed to sunshine in broth for different periods of time, varying from

ten minutes up to four and a half hours. It was found that those cholera cultures which had been kept in the dark killed guinea-pigs in eighteen hours, the same result being also obtained with cultures exposed to sunshine for from ten minutes to two hours. When, however, the insolation was prolonged for three hours, the lethal action was less rapid; whilst after an exposure of from three and a half to four and a half hours they were no longer endowed with any virulent properties, for the guinea-pigs into which they were inoculated suffered no ill effect whatever.

Not only, however, was the virulence diminished and removed by these short exposures to sunshine, but the guinea-pigs which had survived in the above experiments, on being inoculated eight days later with virulent cholera bacilli, were quite unaffected by these doses, which would have proved rapidly fatal to ordinary guinea-pigs. Thus the sunshine had endowed these cholera bacilli with the power of shielding animals from the attacks of their still vicious and evil-disposed companions.

Dr. Palermo also ascertained that no diminution

in the numbers originally present in the broth culture took place during this exposure to sunshine ; but that when it was extended to from six to seven hours, the bacilli (whilst still undiminished in numbers, as shown by the colonies which developed on gelatine plates) were found to have lost their power of motility when examined in drop-cultures under the microscope, whilst those preserved in the dark exhibited the typical lively movements characteristic of these bacilli.

In this connection it is interesting to note some investigations made by Kitasato on the effect of sunshine on the virulent properties of broth in which the tetanus microbe had been grown. In these experiments the broth was first passed through a filter of biscuit porcelain in order to remove all the bacteria present, so that the filtrate was sterile, and contained only the poisonous substances previously elaborated by the tetanus bacillus during its growth in this culture material.

In *diffused* light these tetanus filtrates gradually lost their poisonous properties, but it was a slow and tedious process, for even after standing from nine to ten weeks they were still feebly toxic. On

the other hand, similar filtrates preserved in the dark were still, after being kept for three hundred days, as virulent as when they were originally prepared.

In *direct sunshine*, during which the temperature recorded varied from 35° C. to 43° C., these tetanus filtrates were entirely deprived of all their dangerous properties in from fifteen to eighteen hours.

These interesting results have been quite recently confirmed by two Italian investigators, Drs. Fermi and Pernosi.

In reflecting upon this solar power of destroying bacteria, we are naturally led to inquire as to when and where it comes into operation in nature. It is obvious of course that this action can only go on upon the actual surface of the earth, and that a depth of even a very small fraction of an inch must be quite sufficient to remove bacteria from this potent and lethal agency.

On the other hand, in the case of water, with its great transparency to light, we should anticipate that this destructive power of the sun's rays would penetrate to very considerable depths.

About two years ago, I made a number of experiments on the action of sunshine on the spores of anthrax suspended in river Thames water, both in its raw, unfiltered condition, and after being sterilized by either boiling or passing it through a filter of porous porcelain. In the one case, therefore, the anthrax spores were present along with a number of ordinary water bacteria, whilst in the other sets of experiments they were sole masters of the field, and were not exposed to any competition from other micro-organisms. The flasks containing the anthrax-infected waters were exposed to diffused daylight for seven months; in all cases, however, the anthrax spores were still present at the end of this period. In the sterile waters, the spores had retained their virulence, for white mice inoculated with some of this water which had been standing for seven months died; but it was evident that the virulence had become somewhat abated, for although the anthrax was discoverable in the blood, yet the symptoms were not so pronounced as is usual in cases of anthrax infection. In the unsterile waters, on the other hand, although the anthrax

was still discoverable by special methods, the virulence had been so far attenuated that this anthrax-infected water was unable to kill mice.

In direct sunshine the results were, as we should anticipate, very different. In no case did the spores survive more than one hundred and fifty-one hours' exposure to sunshine, and in nearly all the experiments they were destroyed after from fifty-six to eighty-four hours' insolation. Now although the sunshine was thus effective in entirely destroying the anthrax spores, I was struck by their comparative longevity, for other observers have found that such spores are much more rapidly destroyed, a few hours being sufficient when they are exposed to sunshine in ordinary culture media such as broth, potatoes, etc., in the presence of air.

In endeavouring to ascertain the cause of this phenomenon, I am proceeding by way of synthesis, making various additions to distilled water, and then determining how such additions affect the influence of insolation. I have found already that the bactericidal action of light is very considerably greater in water containing common salt (1, 3, or

10 per cent.) than in distilled water ; whilst, on the other hand, the addition of sodium sulphate in the same proportions has little or no influence in this respect. I have brought together some of these results obtained with common salt in the following table, and the difference obtained in the insulated and dark tubes respectively is shown very clearly :—

ACTION OF SUNSHINE ON ANTHRAX SPORES SUSPENDED
IN WATER.

(PERCY FRANKLAND.)

Number of anthrax spores contained in about twenty drops of water.

SUNSHINE.

	Plain Water.	1% Salt.	3% Salt.	10% Salt.
4 hours' sunshine	16,000	14,000	8,000	5,000
11 hours' ,,	12,000	8,000	3,000	485
21 hours' ,,	378	39	49	0

DARKNESS.

	Plain Water.	1% Salt.	3% Salt.	10% Salt.
4 hours in dark	13,000	13,000	9,000	12,000
11 hours ,,	15,000	13,000	16,000	14,000
21 hours ,,	18,000	15,000	14,000	9,000

I have also found that the previous history of an organism has a very decided effect upon its subsequent behaviour under the trying ordeal of

sunshine, for anthrax spores which have been produced at the ordinary temperature of a room ($18-20^{\circ}$ C.) are far more able to withstand the lethal action of insolation than those spores which have been raised at a considerably higher temperature, *i.e.* $35-38^{\circ}$ C. This is a point which should be carefully borne in mind when comparative experiments are being made on the powers of endurance exhibited under various circumstances by particular micro-organisms. In the above experiments, all the spores employed were produced at the same temperature ($18-20^{\circ}$ C.), and were taken from the same cultivation.

All the experiments to which I have hitherto referred have been made in the laboratory, and with bacteria, therefore, in what may be described as a state of captivity. Before generalizing from such investigations, made more or less under artificial surroundings, we always endeavour to test our results, as far as this is possible, by some crucial experiment made, so to speak, in the open-air laboratory of Nature herself.

There are one or two experiments of this kind which are of interest in this connection, but as

many other factors besides light may and doubtless do contribute to bring about some of the results observed, caution must be exercised in the degree of responsibility which is allotted to the agency of light.

Thus, a reference to the tabulated results of my bacterial examinations of the London water supply at once shows that the microbial contents of the rivers Thames and Lea is very much smaller in the summer, and presumably sunny months, than in the winter, when a minimum amount of light gains access to these waters. Now, although the presence and absence of light undoubtedly has something, and possibly a good deal, to say in bringing about this difference, yet there are other circumstances which cannot be ignored, such as the access of purer spring water to the river in the summer months, and the comparative absence of flood water. In the same manner, the following investigations made on the river Isar above Munich, although of much interest in this connection, must be accepted with a certain amount of reservation.

In order to ascertain the effect of the daylight

on the bacteria in a running stream, two young German enthusiasts, Dr. Minck and Dr. Neumayer, determined to sit a whole night by the banks of the river Isar, from six in the evening until six in the morning, determining the number of bacteria in the water from hour to hour, with the same vigilant zeal that a trusty and responsible nurse watches the movements of a clinical thermometer by the bedside of a patient passing through a perilous fever!

They commenced their watch at 6.15 p.m. on a September evening, when there were 160 microbes in about 20 drops of the river water. At 12 o'clock the number had fallen to 107; but at 1.45 a.m. the microbes began to exhibit their appreciation of the long absence of light, for 380 were found; at 3 o'clock, 460; at 4 o'clock, 520; at 5 o'clock, 510; but at 6.15 they had already felt the fatal finger of dawn, for their numbers had fallen back to 250.

It would obviously be of great interest to have further confirmation of these remarkable results; but the arduous nature of the task will, it is to be feared, damp the ardour of even the most zealous bacteriologist!

But a question of particular interest and import-

ance which at once suggests itself, is the depth in water to which the sun's rays can carry death and destruction to the microbes.

Exact experiments made in the Lake of Geneva have shown that a photographic plate is still affected by the solar rays at a depth of about 553 feet; the intensity of the light at this level being comparable to that which is ordinarily observed on a clear but moonless night.

Experiments on the depth to which the solar rays can penetrate water, and still exert a deleterious effect on bacterial life, have been made in the Starnberger See, near Munich. The site selected for the investigation was the starting-place of the steamers, and the water was not quite clear, the constant plying to and fro of the vessels doubtless rendering the water turbid. At a depth of 5 ft. the bactericidal action of the sun's rays was as strong as outside the water; but already at a depth of $8\frac{1}{2}$ ft. the effect was much less apparent, whilst at 10 ft. it was only just perceptible. Thus the destructive potency of the sun's rays ceases a long time before the light is intercepted by the depth of water it has to traverse.

Some recent experiments made by Dr. Procacci of Naples also exhibit the rapid diminution which takes place in the solar action on bacterial life by the transmission of the rays through water. For this purpose glass cylinders, 24 inches in height, were filled with water, and the sun's rays were made to pass vertically downwards, all light being excluded from the sides of the vessels. Before and after exposure to light the number of bacteria was determined at the surface, in the middle, and at the bottom of the cylinder. The following table shows what results were obtained:—

SUNSHINE PASSING VERTICALLY THROUGH 24 INCHES
OF WATER.
(PROCACCI.)

Bacteria in about 20 drops of water.

<i>June 28, 1893, 11 noon to 3 p.m.</i>		<i>Before exposure.</i>	<i>After 3 hours' ex- posure.</i>	<i>Kept in the dark for 3 hours.</i>
Surface	...	2,100	9	3,103
Centre	...	2,103	10	3,021
Bottom	...	2,140	2,115	3,463

Thus it will be seen that, to start with, the bacteria were very evenly distributed throughout the cylinder, there being practically no difference in the numbers found at the bottom and at the

surface respectively. In the vessel kept for three hours in the dark, on the other hand, a slight increase is observed to have taken place in the bacteria present, and at the bottom of the vessel this is still more noticeable, the number found being larger on account of the tendency which bacteria have when left at rest to become deposited, a process known as sedimentation, and which I have recently shown¹ plays an important part in the bacterial purification of water when stored in reservoirs, etc. Very different is the fate of the microbes suspended in the water placed in the sunshine. Here we see that instead of over 3000, only nine and ten survived; however, this is only the case in the upper layers of the water, for at the bottom of the vessel they have escaped altogether, and although no multiplication has taken place during the three hours' interval, their number remains practically unchanged from what it was before the exposure took place. These experiments, together with those made in the Starnberger See, are of particular importance and interest, because they show very clearly that

¹ *Centralblatt für Bakteriologie*, vol. xiii. 1893.

too great reliance must not be placed upon the agency of light as a means of purifying water.

So much value has been recently attached in Germany to the so-called self-purification of river water in the course of its flow, that the advisability of allowing the sewage of cities of the magnitude of Cologne to pass untreated into the Rhine, has been publicly discussed, on the assumption that in its subsequent flow the morbific material will disappear, light having been cited as one of the agencies materially assisting in the work of destruction.

A very ingenious and pretty method, which admits of many applications and modifications, and may often be employed in experimenting on this subject, was devised about two years ago by Professor Buchner of Munich.

The particular bacteria to be subjected to the action of light are evenly distributed in melted jelly, which is then poured into a small circular dish, the glass cover of which is immediately replaced, and allowed to congeal. After the contents have become solidified, letters or figures of any kind are cut out of black paper, and are attached

to the under surface of the dish, which is then placed in the sunshine, bottom upwards, for the desired time. After the period of exposure has elapsed, the dish is placed in a dark cupboard and kept at a temperature suitable for the growth of the bacteria present. By this means it is obvious that those parts of the dish which are covered by the bits of black paper are protected from the sunshine, and that the latter can only produce its effect on those portions of the surface which are freely exposed, or without this protection. We should expect, therefore, in due course, supposing the exposure to have been sufficient, to find no growths making their appearance in the jelly, except in those parts shielded from sunshine by the strips of black paper. That this is actually the case is shown by the following figures taken from such exposed dishes by Professor Buchner. In the first figure the jelly was sown with large numbers of the *B. coli communis*, an organism normally present in the intestine of man and animals, and very closely allied in nearly all respects to the well-known typhoid bacillus. This dish was placed in diffused daylight for five hours,

and was then kept in the dark, and by referring to the figure we learn what were the black letters

FIG. 50.—A dish containing agar-agar, and sown with *bacillus coli communis*. Exposed to diffused light for five hours. (After Buchner.)

which Professor Buchner attached before permitting the exposure to take place.

In the second figure we find a similar dish sown

with the cholera bacillus, but placed in the sunshine for one and a half hours.

FIG. 51.—A dish containing agar-agar, and sown with *cholera bacilli*. Exposed to direct sunshine for one and a half hours. (After Buchner.)

This pretty way of enabling the bacteria to write, so to speak, their own names on the jelly, I think may best be described as bacterial

autography, or perhaps an even better way of designating these pictures may be the new word which I have ventured to coin for them, of *Photobacteriographs*.

Although we have thus the most abundant evidence that the solar rays, and to a less degree the rays of the electric arc, have this powerfully destructive influence on bacterial life, we are still very much in the dark as to the mechanism whereby this action is brought about.

There is, however, almost complete unanimity that this action of the sun's rays is greatly diminished, if not entirely arrested, in the absence of free oxygen, whilst the simultaneous presence of at least traces of moisture is not improbably also an indispensable factor.

There appears, therefore, strong reason for believing that the whole phenomenon of the destructive action of the sun's rays on bacterial life is due to a process of oxidation at low temperature. Now it has long been known that in many oxidations at low temperature there is frequently formed a considerable quantity of that remarkable substance known to chemists as

peroxide of hydrogen, and which is possessed not only of powerful oxidizing properties, but which is also a strong antiseptic, or destroyer of bacterial life. It has been actually shown quite recently, by Dr. Richardson of Bristol, that this peroxide of hydrogen is really formed in liquids which are exposed to sunshine, and that in these liquids bacteria refuse to grow until the peroxide of hydrogen has been destroyed.

The proof of the formation of peroxide of hydrogen during insolation naturally suggests the question whether the whole bactericidal effect of light is due to this material, or whether it only partially accounts for the phenomenon. This important question is one which it is far from easy to answer, owing to the almost insuperable difficulty of securing conditions under which the generation of peroxide of hydrogen is impossible.

Dr. Richardson in his experiments found that peroxide of hydrogen was formed in urine during insolation, and that it was not produced by the insolation of water, or even of a solution of urea. If, then, the bacteria are suspended in water during insolation, there can be no generation of peroxide

in the liquid. But we have seen that although bacteria are far more resistant to the action of sunshine when suspended in water than in ordinary culture media, it is also equally certain that they are actually destroyed, and sometimes even with great rapidity, when present in water. This at first would appear to demonstrate that the bactericidal effect of light, although accelerated by the generation of peroxide of hydrogen, may also take place without it. But we must not, however, lose sight of the possibility of the generation of peroxide of hydrogen within the cells of bacteria and their spores, and this material, it can be easily conceived, may be formed within such cells suspended in water to which air has access.

The evidence so far to hand would appear to indicate, therefore, that, whilst the generation of peroxide of hydrogen may in many cases be an active factor in the bactericidal influence of light, it is still uncertain whether it is indispensable for the process.

The question obviously raises another and far more general question, which has long been before

the chemical world, viz. as to how far oxidation can take place at all in the entire absence of water-vapour—and the evidence on this larger question goes entirely to show that all apparently direct low temperature oxidations require the presence of water-vapour. And inasmuch as the bactericidal action of light is unquestionably a case of low temperature oxidation, there is the strongest presumptive evidence, as well as weighty experimental evidence, that water-vapour, which practically means the possibility of the generation of peroxide of hydrogen, or some similar material, is essential for its manifestation.

Thus modern scientific investigation is daily enlarging the horizon of our knowledge concerning the stupendous influence which the sun exerts over almost every detail in terrestrial affairs. Each individual science in turn bears witness to the paramount importance of that continuous stream of energy which we receive from its disc, and has only chaos and destruction to foretell of the terrible day when this beneficent flow of energy shall be withdrawn. Even the study of these

minute living organisms, which have attracted so much attention during the past twenty years, has served in the most surprising and unexpected manner to increase our wonder and to further excite our admiration of the marvellous dominion which the sun exercises over our planet. For whilst science has hitherto been principally concerned with those works in which the solar energy is engaged in the building up of vegetable and animal life, we are now able to realize that this energy is also continually being employed in controlling and keeping in their place these vast and restless multitudes of bacterial forms, which are ever ready to seize and utilize for their own purposes the bodies of animals and plants.

Although the close of the nineteenth century is not likely to find us returning to the Sun-worship of the ancient world, we cannot but sympathize with the spirit which dictated the so-called worship of the solar disc which prevailed in Egypt under Amenhotep IV., who is better known as Khuenaten, about 2000 years B.C.; and admire a form of religion which finds itself in material

harmony with the teaching of scientific discovery made nearly 4000 years later.

We shall all, however, endorse the poetic imagery of Plato when he says that "Truth is the Body of God, and Light is His Shadow."

ADDITIONAL CHAPTER.

[1897 and 1899.]

VIII.

RECENT APPLICATIONS OF BACTERIOLOGY.

WE have already referred to the services rendered by bacteriology in the domain of preventive medicine, and we have seen how the great problem of securing immunity from disease which occupied the later years of Pasteur's activity was beginning to enter upon a new phase as illustrated by the experiments on immunity to tetanus or lockjaw, carried out by Kitasato.

In no department of bacteriology has more activity been exhibited during the last few years than in working out the discoveries which have been made in the production and application of antitoxins in the treatment of disease.

Whilst Pasteur's methods depended essentially on submitting the individual to be protected, to

the attack of the disease-producing organism itself, albeit in an attenuated or weakened condition, the new methods of conferring immunity do not involve any contact whatsoever between the individual and the living virus in any shape or form.

As might be expected, this transition was neither accomplished in a single bound, nor by the effort of a single investigator, and it is not surprising that the prestige of being the predominant partner in this great achievement, should have been claimed not only for several different individuals, but that it should have actually become a matter of dispute between the two great rival nationalities of the Continent.

It would be unprofitable to enter into the details of this controversy ; suffice it to say that the first distinct step in the transition was the discovery, to which reference has already been made, that the artificial cultures of pathogenic bacteria can be entirely freed from these bacteria or sterilized, and yet produce their characteristic poisonous effects on injection into animals.

Thus the poison or toxin of the diphtheria bacillus was obtained by Loeffler, who was also

the discoverer of the diphtheria bacillus itself, whilst this toxin was more fully investigated by Roux and Yersin of the Pasteur Institute, as well as by Dr. Sidney Martin. By this discovery the toxins of diphtheria and of several other diseases have been rendered as specific poisons, as are laudanum or the extract of *nux vomica*; for it is now possible to produce some of the characteristic symptoms of these diseases by the administration of these sterile toxins, just as we can produce laudanum poisoning without resorting to the living poppy.

It was further found that animals can be gradually accustomed to the specific toxins, just as human beings can be gradually inured to laudanum or tobacco, and the question then arose as to how such animals which had undergone this gradual habituation to a particular toxin would behave on being subsequently inoculated with the disease-producing organism itself.

On submitting this point to experiment, it was actually found, as we have already learnt, that the animal which had survived a gradual treatment with the bacterial poison, was capable of withstanding the subsequent attack of the virulent

bacteria themselves. This important achievement of securing immunity for an animal without its having had any contact with the disease-producing organism itself, we owe to the labours of Salmon, Roux, Chamberland, and other investigators.

The next step, which is assuredly the most surprising of all, consists in the demonstration that the blood of an animal thus artificially immunized against the toxin of a particular disease, contains materials which can be transferred to another animal, with the result that this animal also becomes thereby protected from the same malady.

This astounding antitoxic property of the blood-serum of an artificially immunized animal was first discovered by Richet and Héricourt, two Frenchmen who were experimenting on rabbits with one of the ordinary abscess-producing bacteria, the *staphylococcus pyosepticus*. They found that rabbits which had received injections of blood derived from dogs which had been previously inoculated with this *staphylococcus*, were protected from subsequent infection with this microbe.

This important step was followed up by Behring and Kitasato, to whom the credit is due of having

shown not only that the blood-serum of animals artificially immunized against diphtheria and tetanus respectively, is capable of protecting from these diseases other animals into which this serum is injected, but that even after these diseases have been actually contracted, they may be cured by the subsequent administration of the antitoxic serum.

The precaution must, however, be observed, that a sufficient quantity of the serum is employed, and that its injection be not postponed until a too advanced stage of the malady has been reached.

The first trial of immune serum in the treatment of human diphtheria was made in von Bergmann's clinic, in Berlin, in the autumn of 1891, but this, together with other trials, were of a tentative nature, and were made with weak serum and insufficient doses.

It was not until early in 1893 that Behring succeeded in obtaining an antidiphtheritic serum of effective strength, and since this time the efforts of numerous investigators have been directed to producing not only serum of yet greater potency, but in sufficient quantity to supply the demand which has arisen for it in all parts of the world.

The supply of this therapeutic serum for diphtheria has already become a commercial undertaking of considerable magnitude, and it is worthy of note how chemical science has again in this, as in so many other matters, come to the assistance of medicine.

It is obvious that the preparation of such serum on any scale must involve the employment of a large staff of highly skilled and scientifically-trained persons, who are not to be collected into any ordinary manufacturing establishment at a moment's notice.

Now, Messrs. Meister Lucius and Brüning, one of those great industrial organizations which are principally to be found in Germany, and in the works of which coal-tar is converted into all the colours of the rainbow, into the perfumes of Arabia, and into many of the most valued drugs of the modern physician, this great firm of coal-tar manufacturers, with its numerous staff of scientific advisers, has seen its way to still further enlarge its works by adding to them vast stables in which large numbers of superannuated horses are passing a comfortable and useful old age in furnishing the

antitoxic serum which is destined to alleviate the sufferings of thousands of young victims to diphtheria.

As in all new departures, opponents have not been found wanting who have vigorously attacked this the latest outcome of bacteriological science. But the statistics which have so far been collected from all parts of the world concerning the application of this antitoxic serum, the preparation of which has been entrusted to competent persons, appear to demonstrate beyond doubt that, anti-diphtheritic serum is a specific curative agent surpassing in its efficacy, according to those best able to judge, all other known methods of treatment of this disease.

Diphtheria is, however, by no means the only infectious disease in which protection has been sought and secured by means of the serum of immunized animals. During the terrible outbreak of bubonic plague in India recently, recourse was had to an anti-plague serum which had been discovered and elaborated at the Pasteur Institute in Paris.

The preparation of this new antidote was the

direct outcome of the discovery by Dr. Yersin, a former student of Pasteur's, of the plague-microbe. It was in the year 1894 that Yersin received a request from the French Government to proceed to Hong Kong to study the plague which had recently broken out there. The French were, not without reason, alarmed for the safety of their colonies in Indo-China, for from Canton, where it had in a few weeks caused the death of 60,000 people, it had been brought to Hong Kong, and the busy commercial intercourse between these cities and Tonkin, and the difficulty of establishing efficient quarantine regulations, gave justifiable cause for fear that French Indo-China would also be overwhelmed by its relentless ravages. Yersin arrived at Hong Kong a few weeks after the plague had commenced its terrible career in that city—a career which had already claimed the lives of 300 Chinese, and which was yet to exact a tribute of over 100,000. Temporary hospitals, he tells us, were being rapidly erected, the ordinary accommodation being wholly inadequate to cope with the dimensions of the epidemic. The disease was almost exclusively confined to the insanitary

Chinese quarters of the city, where the wretched cabins occupied by the natives were often not only without windows of any kind, but were sunk below the level of the ground, which, coupled with the shocking overcrowding that prevailed, converted such dens into plague-incubators of the most dangerous and horrible character. In all its features the disease resembled the historic outbreaks of plague which have in the past so frequently decimated Europe, and the last appearance of which in Europe culminated in the famous Marseilles epidemic of 1720.

Yersin obtained permission to erect a small hut within the precincts of the principal hospital; and here, in a concentrated atmosphere of plague, he took up his quarters, and hastily improvising a laboratory, commenced his search for the mysterious *materies morbi* which was practically sweeping away all before it, the mortality being as high as 95 per cent.

A careful inspection of the infected districts of the city brought to light the curious fact of immense numbers of dead rats lying about in all directions, in the houses as well as in the streets;

but on inquiry Yersin was told that there was nothing unusual in this phenomenon, this rat mortality being recognized as a well-known fore-runner of the plague, the latter usually heralding its advent by attacking animals such as rats and mice, and in the country districts swine and buffaloes, before touching human beings.

An examination of these dead rats showed that their symptoms differed in no way from those which characterize the plague in man, and the extreme susceptibility of these animals furnished Yersin at once with a valuable means of tracking out the virus.

His first step was to make careful examinations of the bubonic material present in the tumours which characterize the disease, and here he discovered immense numbers of a short bacillus which appeared to be almost exclusively in possession of the field. These he found were readily obtained, and could be cultivated with ease in the usual bacterial media. Further investigation showed that these same bacilli were invariably present in the ganglia and liver and spleen of plague patients; that they were, however, rarely

to be found in the blood, and then but in small numbers, and usually only in rapidly fatal cases a short time before death.

Healthy rats and mice inoculated with pure cultures of this *Cocco bacillus pestis*, as it has been scientifically called, succumbed to typical plague symptoms, and Yersin had thus accomplished the first step in his investigation—the identification of the specific virus of plague.

In connection with the remarkable susceptibility of rats and mice to this disease, Yersin found that plague bacteria taken from the bodies of these animals were much more virulent than those grown in ordinary culture media. Thus these animals may serve as hot-beds, so to speak, for the luxuriant propagation of plague virus, converting comparatively innocuous plague bacteria into specimens endowed with highly lethal properties as regards human beings. Dr. Roux has taken advantage of this fact, and to ensure the elaboration of highly virulent cultures of plague bacilli, he encloses them in small bags of collodion, which he introduces into the peritoneum of rabbits. The bacteria are in this manner defended on the one

hand from the attacks of the migratory cells of the body,¹ and are thus not impeded in their growth and development by any inimical influence ; whilst, on the other hand, they are kept constantly supplied with the living humours of the body, which pass through the walls of the collodion bag, and are thus placed in the most advantageous position conceivable for growth and the develop-

¹ This method of cultivating bacteria has been recently successfully applied in the case of a bacterium which had long defeated all attempts to secure its artificial propagation. The microbe of pleuro-pneumonia of cattle has baffled the efforts of bacteriologists to demonstrate it for nearly half-a-century. As long ago as 1850 the virus was known to exist in the liquid exuding from affected lungs, but it could not be isolated. Nocard and Roux have, however, now succeeded in exhibiting this refractory microbe for the first time. They took some virulent matter from a pleuro-pneumonia lung and inoculated it into some sterile bouillon, and placed the latter in capsules of very thin collodion subsequently hermetically sealed. These capsules were introduced into the peritoneal cavity of a rabbit. The collodion wall is an absolute barrier to the egress of the microbe and to the ingress of the cells of the animal, but, as we mentioned above, is perfectly permeable to liquids and dissolved matters. After a while a rich culture of the microbe was found inside the capsule, and experiments already conducted indicate that subcutaneous inoculation of small quantities of these cultures afford protection from the disease.

ment of their fullest possible complement of virulence.

The following figures are taken from one of the photographs which accompanied Yersin's original memoir describing his isolation of the plague bacillus.

FIG. 52.—Plague bacilli from human bubonic material.

FIG. 53.—Plague bacilli grown in broth.

Yersin was at first of opinion that rats were the principal disseminators of the disease, for healthy mice shut up with a dead plague-stricken rat, rapidly developed plague and died; but he noticed later the curious fact that, in the little room where he carried out his *post-mortem* examinations, immense numbers of dead flies were scattered about in all directions. Determining to ascertain, if possible, whether this wholesale slaughter of flies had any connection with plague infection, he

took some of these insects, and first removing the head, wings, and feet, he pounded up their bodies in broth. A subsequent examination of the liquid exhibited masses of bacilli closely resembling the now familiar plague microbe, and that this was not only a superficial resemblance was proved by inoculation of this broth into mice, when the latter succumbed to plague. That flies may materially assist in the dissemination of plague was thus proved beyond doubt ; and yet another instance was thus furnished of the *rôle* which these insects may, and undoubtedly do, play in the spread of disease, a fact which may well be borne in mind in the wards of hospitals and in the sick-room. With the slender accommodation and primitive means at his command in Hong Kong, Yersin was unable to carry his investigations to the next stage of preparing an anti-toxin for the treatment of plague, and he therefore forwarded some of his plague cultures to the Institute in Paris ; and here later, under the superintendence of Roux and others, an anti-plague serum was elaborated, which is now included amongst the series of anti-toxins regularly supplied by the Pasteur Institute. Just

as Yersin's discovery of the plague toxin led to the production of its anti-toxin, so Kitasato's researches, which we have already referred to, on the toxin of tetanus or lockjaw, were followed by the discovery of an anti-tetanic serum. Numerous instances have been recorded in scientific journals in which this tetanus anti-toxin has been employed, and whilst in some cases success has undoubtedly followed its application, in others results of a highly disappointing character have been received. The clue to the failure of the anti-toxin to act as such, successfully eluded for some time the patient search of the investigator, but a series of remarkable experiments conducted by Roux on this subject have now opened up a new method of approaching the study of anti-toxins, which promises to throw considerable light on the complicated problems of immunity.

Tetanus has long been recognized as a disease which specially affects the nerve-centres of the body, and this fatal affinity which exists between the tetanus toxin and nerve-substance has been illustrated in a very important manner by Dr. Roux. An animal infected with tetanus in the

ordinary way by introducing the poison under the skin, does not succumb to the disease for some days, but if a dose of the toxin, only one-twentieth the quantity of that usually employed, be inoculated direct into the brain, the animal falls a victim to tetanus in a few hours.

This difference in the susceptibility of an animal to the poison, according to its mode of introduction into the system, would seem to indicate that a good deal of the toxin when subcutaneously introduced fails to reach the nerve-centres, it having been arrested or modified in some manner during its journey thither. Dr. Roux has shown in regard to other poisons, how the direct contact of the toxin with the nerve-centres reveals a sensibility on the part of an animal to a substance from the action of which under ordinary circumstances it has been usually regarded as immune.

Thus rats can withstand a dose of diphtheria toxin sufficient to kill several rabbits, and it was, therefore, inferred that these animals possessed a special immunity from this disease. If, however, a very small quantity of diphtheria poison, insufficient to produce under ordinary circumstances

even a slight swelling at the seat of inoculation, be introduced directly into the brain of a rat, the animal succumbs to the action of the toxin. The same remarkable phenomenon has been observed with reference to morphia and rabbits, these rodents being highly refractory as regards the action of this drug subcutaneously introduced ; when, however, a minute quantity of this material is cerebrally inoculated, the animal falls a victim to it.

It is obvious, therefore, that the nerve-centres of the body in all the above cases are not endowed with immunity under ordinary circumstances from the lethal effect of these substances. Now the interesting question arises whether, in the case of animals artificially rendered immune to the action of the tetanus toxin, the nerve-centres have likewise become endowed with a power of resisting this poison, or is the undoubted immunity which may be acquired by animals, due to the system having become capable of destroying or counter-acting in some manner the poison before it can reach these nerve-centres, the latter being still in themselves defenceless and at the mercy of the toxin ?

Dr. Roux has given us the answer to this

question in a most emphatic manner—he has taken animals artificially perfectly protected from tetanus poison introduced subcutaneously, and has succeeded, through bringing a trace of the toxin in direct contact with their nerve substance, in procuring their death in the same manner as if they had been totally untrained to resist the infection. Thus an animal's artificial as well as natural immunity to the action of a particular toxin is not dependent upon any inability of the nerve-centres themselves to react to the poison, but upon a condition either natural or artificial in the animal's system through which the toxin is directly impeded from reaching its destination.

We now come to the most important part of the inquiry—if the toxin acts so powerfully directly upon the nerve-centres, what may be the action of the anti-toxin if brought into intimate contact with these same centres? May we not possibly, by altering its mode of application, increase the efficiency of the anti-toxin? This is what Dr. Roux has actually succeeded in doing, and by substituting cerebral for subcutaneous inoculations of the anti-tetanic serum, employing a few drops only of the

latter, he has succeeded in arresting the course of the disease and saving the lives of animals, whilst other similarly infected animals into which large quantities of protective serum were only *subcutaneously* introduced succumbed to the disease. "Il ne suffit pas de donner de l'antitoxine, il faut la mettre au bon endroit," in these few words Dr. Roux summarizes the results of researches, the far-reaching and possible application of which in the prevention of disease it is difficult to over-estimate, opening out as they do an entirely new avenue for the investigation of toxins and anti-toxins.

But the possibilities of securing protection by means of the serum of immunized animals extend even beyond the boundaries of infectious disease. If the serum of an animal rendered insusceptible to a particular disease can counteract the poisons manufactured by the specific bacteria of that disease, may it not also be possible to counteract in the same way poisons that have a non-bacterial origin altogether? The answer to this important question has been given by Dr. Calmette in respect of snake-poison.

It was whilst acting as Director of the Bacterio-

logical Institute of Saigon, in Cochin China, that Calmette first commenced his experiments on the neutralization of serpent venom in the animal system.

He had exceptional opportunities in the matter of a supply of this material wherewith to carry out his investigations, for a village in the neighbourhood of Bac-lieu (Cochin China) was attacked in the autumn of 1891 by a band of venomous serpents belonging to the species known as *Naja tripudians*, or "Cobra di capello." The heavy rains and subsequent inundations drove these terrible reptiles to take refuge in the huts of the natives, of whom as many as forty were severely bitten. No fewer than ninety of these cobras were forwarded in a barrel to the bacteriological laboratory, out of which forty arrived alive, and served to furnish the Institute with serpent-venom in quantity such as rarely has fallen to the lot of a scientific investigator. Several of the reptiles were at once sacrificed to secure their venom-glands. That to obtain an adequate supply of venom offers as a rule considerable difficulty in the carrying out of scientific investigations with it, may be gathered from the fact that the venom-glands of a full-grown cobra

are about the size of shelled almonds, and each gland contains but about thirty drops of a transparent limpid liquid, in which is embodied, however, a toxin of extraordinary strength.

The first step which had to be taken was to ascertain within as narrow a limit as possible the exact degree of toxic power inherent in the venom. As was to be anticipated from the fatal results which have gained for this cobra so fearful a reputation, its toxic strength is most remarkable in its intensity. Thus a single drop of an emulsion produced by pounding up eight glands in 300 grammes of distilled water is sufficient, when introduced into the vein of a rabbit's ear, to kill it in five minutes. All the mammals to which Calmette administered this venom, such as monkeys, dogs, rabbits, guinea-pigs, rats, succumbed more or less quickly according to the size of the dose. Small birds and pigeons also die very rapidly, but the domestic fowl is more fortunate, being somewhat less susceptible. Frogs also fall a prey to it, but they are far more refractory than rabbits, for it takes thirty hours to kill a frog with a dose of venom which would infallibly destroy a rabbit in

ten minutes. Toads, however, do not enjoy the same power as frogs of resisting the lethal action of this substance, for they die more quickly than the latter, and it makes also short work of lizards and chameleons. Fish form no exception to the rule, and even invertebrates such as leeches succumb to minute traces of venom. For some time it was believed that the only creatures which could entirely resist the action of this poison were serpents, both poisonous and non-poisonous. Calmette was led to this conclusion because, although he inoculated such large doses as ten drops of venom into cobras as well as harmless snakes, it produced absolutely no effect, but continuing his experiments, and employing very much larger quantities, he succeeded ultimately in persuading reptiles to succumb to its action. The lethal dose, however, for serpents is roughly estimated to amount to three times the quantity of venom normally present in their respective poison glands. These animals, although very refractory, are not, therefore, absolutely immune from this toxin.

There are, however, some animals other than reptiles which enjoy a relative although not abso-

lute immunity from snake poison, and amongst these may be mentioned swine, hedgehogs, and the mongoose. Swine, it is well known, will greedily devour reptiles, and in some countries they are specially trained up and employed for this purpose. Of particular interest, however, are some experiments which were carried out to test the traditional immunity from this toxin ascribed to the mongoose.

Artificial inoculations of cobra venom into this animal have indeed fully substantiated all the observed facts as to its remarkable immunity from this poison. A dose sufficient to kill a large rabbit in three hours was absolutely without effect; only when the venom was introduced in quantities amounting to as much as eight milligrammes was it followed by fatal results.

The remarkable immunity from snake venom with which the mongoose is endowed has rendered it very useful in sugar plantations, where it is largely employed to keep down the serpents and rats which abound there, for this carnivorous little animal is extremely partial to such prey. Attempts have been made by sugar planters to introduce them into Martinique, where they are not found in the wild state as in the Island of Guadeloupe.

Six specimens of the mongoose were forwarded to Calmette from Martinique, and these particular animals, it was stated, had never been seen set at liberty since they were imported, so that they had had no previous experience of snakes or venom. On arriving at the laboratory, one of these little creatures was placed in a glass cage along with a large cobra. The cobra, at once rising up and dilating its neck, darted with fury upon the mongoose, but the latter, thanks to its extraordinary alertness, escaped being caught, and took refuge, stupefied and terrified for the moment, in a corner of the cage. This stunned condition, however, did not last long, for just as the incensed cobra was preparing to make a fresh attack upon its insignificant little victim, the latter, with wide-open mouth, rushed and jumped upon the head of its enemy, viciously bit through its upper jaw, and broke its skull in a few seconds. Thus, although in size but a little larger than a squirrel, this tiny creature was, through its remarkable agility and prowess, more than a match for a cobra two yards long!

In estimating the toxic strength of serpent venom it is, therefore, necessary not only to take

into account the nature of the animal into which it is introduced, but also to bear in mind that the venoms of different species of reptiles vary in the degree of toxicity possessed by them, whilst the venom derived from one and the same reptile also differs in this respect according to the condition of the animal at the time of collecting the venom. It appears that during fasting the venom becomes much more toxic in character, whilst the longer the interval which elapses between two successive bites the more virulent is the venom. These observations made in the laboratory are in accordance with what has been long known in France with respect to indigenous vipers—that their bites are far more dangerous and far more fatal in the spring, after the winter period of torpor is over, than in the autumn. Venoms part very reluctantly seemingly with their toxic properties, for, unlike the bacterial toxins, they can stand exposure to considerable temperature without injury to their virulence. In this respect bee poison resembles viper venom, for exposure to comparatively high temperatures is incapable of destroying the toxicity of this substance also.

Just, however, as the toxic power of reptile venom differs according to its source, so its sensitiveness to heat-exposure varies in different snakes. Thus whilst an exposure of ten minutes' duration to a temperature of 80 degrees Centigrade will remove the toxicity of viper venom, the venom of the so-called "tiger-snake" of Australia will withstand a temperature of from 100 to 102 degrees Cent. for ten minutes, only finally relinquishing its lethal properties when this exposure has been prolonged for twenty minutes.

The effect of sunshine on cobra venom is, however, very marked: thus a pigeon was inoculated with about thirty drops of venom which had been exposed to the sun's rays for fourteen days, and it survived; whilst another pigeon inoculated with a little over six drops of similar venom which had been kept during this time in the dark, died in a quarter of an hour. The power of insolation to modify the virulence of bacterial poisons has been previously referred to in the case of cholera and tetanus toxins in the chapter on the action of light on micro-organisms.

Age exerts but little influence in reducing the

virulence of venoms, for they may be preserved for over a year, and yet prove as fatal as on the day of collection ; when stored for several years, however, the toxic properties are diminished, but they are not by any means entirely destroyed.

Researches of a most elaborate character, of which the above is but the briefest indication, were necessary to determine as precisely as possible the character of reptile venom before the next great step could be undertaken—the elaboration of an antidote.

The importance of this inquiry will be appreciated when we realize that in India alone more than 22,000 persons and 60,000 head of cattle annually fall victims to snake-bites.

One of the circumstances which renders the successful treatment of snake-bites so difficult a problem is the rapidity with which the venom becomes absorbed by the system, which is well illustrated by the following experiment :—A rat was inoculated with venom near the tip of its tail ; *one minute later* the latter was cut off a short distance above the point of inoculation ; but this operation was quite unable to save the animal's life, for even

in that brief interval the poison had already travelled too far, and a few hours later claimed its victim.

It is obvious, therefore, that to effectually cope with so powerful and active a toxin, its antagonist or anti-toxin must be endowed with properties of even superior force and subtlety, and to elaborate a substance capable of undertaking so weighty a work was the ambitious task which Calmette set himself to accomplish.

Taking into consideration the intensely toxic character of serpent venom, it will be at once apparent that the first step, that of artificially immunizing animals from this poison, was no easy one to accomplish, for the process depends upon training an animal to gradually withstand larger and larger doses of the venom, and the danger was ever present of the animal succumbing before its serum had acquired the requisite pitch of protective power to render it of service as an anti-toxin.

Dr. Calmette tells us that he carried out a very large number of experiments before he met with success. We cannot here describe his efforts, suffice it to say that at length his labours were

rewarded, and the following extract from one of his memoirs describes briefly the methods which he now adopts for this purpose.

"The best method of procedure for the purpose of vaccinating large animals destined to produce anti-venomous serum consists in injecting them from the outset with gradually-increasing quantities of the venom of the cobra mixed with diminishing quantities of a 1 in 60 solution of hypochlorite of lime. The condition and the variations in the weights of the animals are carefully followed, in order that the injections may be made less frequently if the animals do not thrive well. Quantities of stronger and stronger venom are in turn injected, first considerably diluted, and then more concentrated; and when the animals have already acquired a sufficiently perfect immunity, the venoms derived from as large a number of different species of snakes as possible are injected. The duration of the treatment is of considerable length—at least fifteen months—before the serum is sufficiently active to be used for the purposes of treatment."

Undoubted evidence of the efficiency of

Calmette's cure for snake-bites has now been obtained, not only from the investigations carried out with this anti-venomous serum at the discoverer's own laboratory at Lille, but also from statistics and reports emanating from all parts of the world ; and it is highly satisfactory to learn, that Indian medical authorities have arranged for its production as part of the routine work carried on in the new great bacteriological institute at Agra.¹

The protective potency of this anti-venomous serum may be gathered from the fact that it suffices to inject a rabbit, for example, with a quantity amounting to about one two-hundred-thousandth of its weight to ensure the latter acquiring complete immunity from a dose of venom capable of otherwise killing it in twelve hours. In estimating the dose of anti-toxin necessary to protect an animal from venom, consideration must be had to the natural susceptibility of the animal.

¹ Calmette mentions that in the case of horses, sheep, dogs, oxen, etc., bitten by venomous snakes, even if already advanced symptoms of poisoning have declared themselves, it is nearly always possible to save the animal's life by injecting a dose of anti-venomous serum beneath the skin of the belly or shoulders.

to this poison. Thus a guinea-pig weighing 500 grammes requires twelve times as large a dose of anti-toxin to protect it from the venom as a rabbit weighing two kilogrammes. Again, to immunize a fowl against a large dose of cobra venom, it is necessary to inoculate about ten times as much of the anti-toxin as is required to immunize a horse, both the guinea-pigs and fowls being respectively far more susceptible to venom poison than rabbits and horses.

The period of time during which an animal remains refractory to venom varies according to the quantity of the poison it has been finally trained up to withstand. Thus a rabbit which had been rendered capable of receiving with impunity in one dose venom sufficient to destroy 120 ordinary rabbits, after the lapse of eight months, during which it had received no special treatment whatever, was still able to withstand a dose sufficient to kill three rabbits in twenty minutes. Guinea-pigs, on the other hand, which, owing to their susceptibility to this poison, it is impossible to train up to withstand anything but the smallest doses of venom, only retain a condition of

immunity for very short periods of time, it usually disappearing in less than a month.

This, it must be remembered, is the case with immunity induced by successive and increasing administrations of the toxin, the immunity procurable by the injection of the anti-toxin is of very much smaller duration, lasting usually only two or three days, according to the quantity of serum which the animals have received. By daily injecting serum for a fortnight into rabbits, for example, these animals are enabled to preserve a condition of immunity for from twenty to twenty-five days.

Although, however, the period during which anti-venomous serum can confer immunity is very brief, its action is extraordinarily powerful and rapid.

Thus, if about fifty drops of anti-venomous serum be inoculated into the marginal vein of a rabbit's ear, it at once confers upon the latter complete immunity from snake-poison. Immediately after the injection of the serum, venom sufficient to destroy an ordinary rabbit in a quarter of an hour may be injected with impunity into the vein of the other ear.

But not only are the *protective* powers of this serum so remarkable in their degree, but its *curative* powers, a much more difficult property with which to endow a serum, are extraordinarily intense, as may be gathered from the following example. Four rabbits were inoculated with a quantity of venom calculated to destroy them in the space of two hours ; one of these four animals was abandoned to its fate, but the other three received, practically at the eleventh hour, viz. just fifteen minutes before the expiration of the calculated two hours' respite, an intravenous injection of a small quantity of anti-venomous serum, only amounting to one-four-hundredth part of the weight of each animal respectively. The rabbit which only received the venom died at the end of two hours, whilst the other three remained in perfect health.

Here then we have an anti-toxin endowed with all the powers which the nature of the toxin against which it has to do battle demands of it, and Calmette and his assistants may justly be proud of the triumph which has followed their

most arduous investigations in the elaboration of a cure for snake-bites.

Before passing on to the consideration of other poisons of a non-bacterial origin against which the resources of modern science have also secured an immunizing agent, we must call attention to a very remarkable characteristic in connection with this anti-venomous serum, and this is its ability to protect from quite another toxin, *i.e.* the poison of scorpions.

That toxins of various origins may be counteracted by one and the same anti-toxin is a subject to which Calmette has devoted special attention, and it is obvious what important bearings this discovery of the wider beneficent application of one and the same substance may have in the development of the science of preventive medicine. We shall have to return to this important point later, and will now proceed to give a short account of the success which has followed the endeavour to provide an anti-toxin in the case of a very powerful poison of a totally distinct character, that known as *abrine*, and derived from the active

principle of the seeds or beans of a leguminous plant common in India and South America. Particular interest attaches to this vegetable toxin, as it is one which is largely used in India by the natives as a means of wreaking vengeance on their enemies by poisoning their cattle. To effect this sinister purpose with both secrecy and certainty poisons are employed, which, while on the one hand of great strength, are so subtle in character as to render detection a matter of much difficulty.

Serpent venom is one of the materials employed, and the practice of administering it consists usually in soaking rags in the poison and thrusting them into the rectum of cows. Some of these rags have been recently examined, and it has been proved by inoculations into animals that the lethal substance they contained was serpent venom.

Another method of destroying cattle consists in the inoculation of the animals with abrine. For this purpose small bits of wood shaped like miniature clubs are fitted with tiny pointed rods composed of a hard greyish substance. These crude instruments are so small that they can easily be concealed in the palm of the hand, and armed

with them a native scratches his enemy's cattle in several places, and although hardly anything external is visible, the pointed rodlet penetrates the skin and is broken off, and the poison is thus placed *in situ* and rapidly does its lethal work. Some of these rodlets were sent to Calmette, and he was able by experiments on animals to prove beyond doubt that the deadly principle they contained was abrine.

This substance is highly toxic in character, and very few animals can resist its action to any extent, and this relative immunity is restricted apparently to hedgehogs, fowls, tortoises, frogs and adders. One milligramme of abrine is sufficient to kill a rabbit in forty-eight hours, but it requires a dose of ten milligrammes to destroy a fowl or hedgehog in that time, whilst a tortoise demands as much as thirty milligrammes before it will succumb.

Although the same degree of therapeutic interest is not attached to the elaboration of an anti-toxin of abrine, its production and study have led in Calmette's hands to some very interesting results.

Whilst he has shown that it is possible to artificially confer immunity from abrine poison on such highly susceptible subjects as rabbits, and that the blood serum of these immunized rabbits is capable of protecting other animals from the action of the poison, he has clearly demonstrated that the blood of animals *naturally* immune to this toxin has no inherent power to bestow immunity from the action of abrine upon other susceptible animals.

It has long been known in regard to poisons of a bacterial origin, that the natural immunity to a lethal substance enjoyed by one species of animal cannot be normally handed on by means of its serum to another animal, and Calmette has now confirmed this observation in respect of the vegetable poison abrine. But he has gone further, and has shown that although warm-blooded abrine—refractory animals, such as fowls, can be trained to produce an anti-abrine serum, cold-blooded refractory animals such as tortoises and frogs cannot under any circumstances be induced to elaborate an abrine protective serum.

The solution of these problems has yet to be

found, and it is only by the continued patient prosecution of researches such as those we have been considering that we can ever hope to master the intricacies of the mechanism which controls immunity.

Before closing this brief review of what has so far been achieved in this great domain of preventive medicine, mention must be made of some remarkable investigations which have resulted in a further unexpected addition to our already long list of toxic substances.

This addition has involved the blood of eels being relegated to the category of poisons, and that this classification is justified will be granted when we learn that about a dozen drops of this fish's blood inoculated into a dog weighing about fourteen pounds will destroy the latter in less than ten minutes, whilst pigeons, rabbits, and guinea-pigs similarly treated, only with smaller quantities, also invariably succumb to its lethal action.

Public confidence in the eel as an article of food need not, however, be shaken, for it is satisfactory to learn that the researches which on the

one hand condemn eels as living generators of a highly poisonous substance, on the other hand allay any alarm which they may have reasonably raised by showing that this toxic principle is entirely destroyed in the processes of digestion, and that, therefore, taken through the mouth it is harmless, and only when introduced into the system by inoculation beneath the skin or injected into the peritoneum can it assert its dangerous properties. Inasmuch as this eel-toxin possesses a lethal action when introduced into the peritoneal cavity, it differs from tetanus toxin, which can be introduced in this manner into guinea-pigs without injury to them. It would be interesting to know, in the light of Roux's researches on the relationship between certain toxins and nerve substance, how this eel poison affects the nervous centres of the body, but so far no experiments have been recorded in this direction.

Eel-poison also rapidly parts with its toxic character on being heated as well as by being kept for more than a few days. But another and very remarkable method of mitigating the

virulence of this poison, although one which for practical purposes is hardly likely to come into use, consists in introducing subcutaneously into an eel some hours before it is killed some anti-venomous serum. This procedure effects a remarkable reduction in the degree of toxicity possessed by eel-blood. Thus an eel weighing about six ounces received subcutaneous injections of five cubic centimetres of anti-venomous serum ; after the lapse of four-and-twenty hours it was killed and bled, and its serum inoculated into animals in the usual way. But whereas two cubic centimetres of normal eel-blood sufficed to kill a guinea-pig, this eel's blood had to be administered in twice that quantity to produce a fatal result, so that it is apparent how considerably its toxic character had been modified.

Just as animals have been artificially immunized from so many other toxins, so in the case of eel-poison it has been found possible to protect animals from its lethal influence. If eel-blood be heated to 58 degrees Centigrade it may be inoculated with impunity into animals, and the

latter moreover acquire through its injection an immunity from the ordinary effects of eel-poison, which condition lasts at least three days.

But this heated eel-serum is not only capable of protecting animals from subsequent doses of eel-poison, but it is also endowed with the remarkable power of shielding animals from the deadly action of viper venom. The full complement of protective power obtainable from this heated eel-serum is only able to slowly assert itself, for it is necessary for a period of as long as twenty-four hours to elapse after its introduction to ensure the animal's system being thoroughly impregnated with it, and enable it to withstand a lethal dose of viper venom. This contrasts very markedly with the rapid action which we have seen characterizes protective anti-venomous serum.

But although this heated eel-serum may *protect* an animal from the venom of vipers or the toxic principle contained in ordinary eel-blood, it is quite incapable of stretching forth a healing hand after the poison has begun its work in the system; it cannot exert any *curative* properties, and, therefore, this treated eel-serum cannot be legitimately

enrolled with the anti-toxins which have been elaborated, for to be worthy of such rank, a substance must be capable of wielding both protective and curative powers.

Considerable interest attaches to the fact that anti-venomous serum acts as an anti-toxin towards eel-poison, for thus we have another instance of a substance being applicable as an anti-toxin to a toxin of a totally distinct character. Anti-diphtheritic and anti-tetanic serums, however, are not endowed with this power as regards eel-poison. So far we have only dealt with the immunizing properties of heated eel-serum, but animals have also been artificially immunized by the administration of gradually increasing doses of ordinary untreated eel-serum, just in the same way as immunity has been secured for animals as regards serpent venom.

Animals thus accustomed to eel-poison are capable of yielding a serum which possesses all the features of a true anti-toxin, exercising both protective and curative powers as regards eel-toxin; and here again we have an example of an anti-toxin acting as such towards a toxin of

different origin, for anti-eel-serum can immunize animals from the effects of viper venom as well as viper-blood.

This last item in its stock of beneficent properties brings us to the curious fact, that whilst viper blood is also poisonous, it is not nearly so toxic as eel-blood, the latter being no less than three times as powerful a poison as the blood of the most vicious viper.

To Calmette we owe the knowledge that the blood of poisonous snakes is toxic, for in the days when it was supposed that reptiles were immune to the action of venom, the theory was propounded that this immunity depended upon the presence in the blood of such animals of some anti-toxic substance. Calmette, however, showed that far from any such beneficent substance existing in the blood of reptiles, the latter contained a poisonous principle capable of killing animals.

The foregoing pages will sufficiently indicate not only what great progress has been made in building up a science of preventive medicine, but also how much yet awaits to be accomplished in this vast and important domain of knowledge.

We are as yet but on the threshold, and who shall say what triumphs await the labours of generations to come; but however great the achievements that may be theirs, in the future as in the present, science must ever recognize the debt of gratitude it owes to the genius of Pasteur.

IX.

BACTERIOLOGY AND AGRICULTURE.

THE numerous and important researches which have been carried on so vigorously in all parts of the world in the science of preventive medicine, and which have had for their object the relief of human suffering and the saving of valuable lives, have not by any means exhausted the ingenuity or enthusiasm of bacteriological investigators. In the rush after toxins and anti-toxins, the interests and prosperity of a section of society, whose grievances have of late been so frequently held up to public notice and commiseration, have by no means been lost sight of. Bacteriology in the past has not by any means been unmindful of agriculture in its various applications, and we have seen, already, how it has elucidated some very important problems in relation to nitrification

and other matters of fundamental consequence to those concerned with the cultivation of the soil.

Special attention was directed to the remarkable investigations of Messrs. Hellriegel and Willfarth on the assimilation of atmospheric nitrogen by leguminous plants through the agency of certain bacteria flourishing in and around their roots, whilst reference was made to the experiments on the same subject by Professor Nobbe, who not only confirmed these earlier observations, but showed that each particular leguminous plant is provided with its particular micro-organism, which leads to the fixation of free nitrogen.

Investigations, the interest of which appeared until recently to be limited by the horizon of the laboratory, have now, however, yielded practical results which are in a position to face the inexorable tribunal of the commercial world.

Dr. Nobbe, together with Dr. Hiltner, has been zealously pursuing his researches on the isolation of those particular bacteria upon which he found the assimilation of free nitrogen was dependent.

Up to the present time pure cultivations of organisms derived from the nodules found on the

roots of seventeen different leguminous field crops have been obtained :—

1. Pea (*Pisum sativum*) } Pea family.
2. Field pea (*Pisum arvense*) }
3. Vetches or tares (*Vicia sativa*) }
4. Field or horse-bean (*Vicia Faba* or *Faba vulgaris*) } Vetch family
5. White lupins (*Lupinus albus*) }
6. Yellow lupins (*Lupinus luteus*) } Lupin family
7. Blue lupins (*Lupinus angustifolius*) }
8. Red clover (*Trifolium pratense*) }
9. White clover (*Trifolium repens*) } Clover family
10. Alsike (*Trifolium hybridum*) }
11. Trifolium or crimson clover (*Trifolium incarnatum*) }
12. Cow-grass (*Trifolium pratense perenne*) }
13. Trefoil, yellow or "hop" clover (*Medicago lupulina*) } Clover family
14. Lucerne (*Medicago sativa*) }
15. Sainfoin (*Onobrychis sativa*) }
16. Serradella (*Ornithopuss sativus*) }
17. *Lathyrus sylvestris*.

Others will shortly be added to the list, e. g. Kidney-vetch (*Anthyllis vulneraria*) and Bokhara clover (*Melilotus alba*).

Although microscopically the organisms obtained from the nodules of all these different leguminous plants are practically indistinguishable, yet in their relation to plants other than those from which they were originally derived, very pronounced

differences exist in the services which they are in a position to render to such alien plants. These so-called "pure cultivations" of nodule bacteria are rendered easily available for transport and use by being placed in glass bottles of from 8 to 10 oz. capacity. At the bottom of these bottles a small quantity of agar-gelatine provides the material upon which these bacteria maintain their existence until their particular powers are called into requisition.

These bottles on receiving each their special bacterium are then sealed and kept in the dark to avoid the deleterious action of light.

Professor Nobbe has endowed all these pure cultivations with the collective title of "Nitragin," from 'nitro,' short for 'nitrogen,' and the Greek word *ἀγείν* or Latin *agere*, make active.

The production of Nitragin on a commercial scale has already been commenced by the same great firm of colour manufacturers, who have devoted so much attention to the elaboration of diphtheria antitoxic serum, and under the direction of Dr. Gesell, a former assistant of Dr. Nobbe's and associated with him in the inquiry, the work

is now being vigorously pursued at the Höchst Farbwörke.

Each bottle bears a differently coloured label, according to the kind of crop it is intended for, and also the German and the botanical name of the plant.

The contents of a single bottle are sufficient to inoculate about half-an-acre of land on which the crop is to be sown, and at present each bottle costs about half-a-crown. Thus the extra cost of using Nitragin would amount to about five shillings per acre.

If you examine one of these bottles all you will see is about an inch and a half depth of a lightish brown jelly, through which a white growth or mould ramifies in all directions. As, however, this insignificant appearance is due to a living or organized ferment, great care must be taken in the handling of it that the vitality of these living particles is not destroyed. For this purpose the precaution must be taken of never letting them experience a heat greater than the temperature of the body, about 98° Fahrenheit (37° Cent.), neither must they be exposed to a strong light.

Neglect of these warnings will bring about the destruction of the bacteria, and thus render them absolutely worthless ; on the other hand, if they are carefully treated they will retain their efficiency for an indefinite time. Nitragin may be used for practical agricultural purposes in two different ways. Thus, the seed may be inoculated direct, which is done by bringing the latter by means of water in contact with the Nitragin ; or some of the soil of the field, on which the crop is to be sown, may be inoculated with the Nitragin, and then this soil may be spread over the plot and worked in to a depth of about three inches. First of all, the contents of the bottle must be rendered liquid, which may be done either by allowing the bottle to stand in a warm room (always bearing in mind the injurious action of strong light), until the jelly has liquefied ; or the bottle may be placed for a short time in *lukewarm* water, for care must be taken, as before mentioned, that the temperature is not allowed to rise above 98° Fahrenheit.

The following are the directions which are supplied with Nitragin for the guidance of those employing it :—

"I. FOR INOCULATING THE SEED DIRECT.

" To every half acre of land to be sown with the crop, take $1\frac{1}{3}$ pint of water in a vessel, and pour into it the liquid contents of one bottle. In order to completely empty the bottle, shake up some of the water with the liquid contents of the bottle, so that the whole gets well mixed, and then pour it into the vessel containing the water. With the water thus prepared, sprinkle the seed thoroughly, and work the heap with the hand (in the case of larger quantities with a shovel), so that every seed is moistened.

" If there be not water sufficient, add more, but speaking generally, $1\frac{1}{3}$ pint is enough for small clover-like seeds. Dry the seed by mixing it with some dry sand or fine earth taken from the field that is to be sown.

" Avoid excessive dryness or dustiness, and do not expose to bright sunshine.

" Sow in the usual way.

"2. FOR INOCULATING THE SOIL.

" Instead of inoculating the seed direct, it is rather

better to effect this purpose by inoculating the earth of the field that is to be sown. To do this, for each half acre of land that is to be sown, take 56 lbs. of earth from the field, and pour the contents of the bottle over it as directed before, but using very much more water. In this way the earth will be inoculated. Let the earth dry in air, or, if necessary, add more dry earth, then spread the whole evenly over the surface to be sown with seed, and work it into the soil to a depth of about three inches. Sow the seed as usual."

As regards these two methods of applying Nitragin, Dr. Nobbe considers the inoculation of the soil the better, although the other may be more convenient, for by this means the organisms are more certain to come in contact with the rootlets. If the organisms remain merely as a coating over the seed, they may possibly miss finding their way to the rootlets; but if they are distributed throughout the soil, the rootlets in passing through the inoculated soil are almost certain to come in contact with some of the organisms.

This is a subject, however, which will doubtless furnish material for subsequent investigation.

The practical advantages claimed for the use of Nitragin may be summed up as follows:—

1. That every single seed is surrounded with a covering of bacteria, which, after germination, penetrate into the root-hairs and begin their activity in collecting nitrogen, so that without nitrogenous manuring and even in soils poor in nitrogen a good yield is assured.
2. That through the activity of the bacteria, the soil becomes richer in assimilable nitrogen, which goes to benefit the succeeding crop also.
3. That the disadvantages of the method heretofore used, of inoculating with crude earth, are avoided.
4. That a manuring with nitrogen in the form of nitrates, ammonia-salts, etc., is rendered quite superfluous.

Trial experiments on a practical scale have already been commenced in this country as well as on the Continent with this new bacterial stimulant, and the results of such field trials next year will be awaited with the greatest interest.¹

¹ The following extract from a letter which I recently received from Dr. Nobbe is of interest in this connection:—

The figure opposite is taken from a number of the *Landversuchs-Stationen*, which contains a detailed account of Nitragin; it illustrates by contrast, very beautifully, the beneficial effect produced by the introduction of the suitable nodule bacteria in the one case and their absence in the other.

Bacteriology, however, has not only been busy working out scientific methods for assisting the agriculturist in raising his crops, but it has also

“In the summer of 1896 inoculation experiments in the open field were carried out in Germany on hundreds of farms, and we have had the satisfaction of learning that in more than 30% of the cases, satisfactory results were reported. This is far more than we had ventured to hope for, as *a priori* it was to be expected that during the first year various mistakes would be made in the practical application of quite new methods; for example, that fields would be inoculated which already contained the necessary bacteria in sufficient numbers, or were already so rich in assimilable nitrogen compounds, that the actual effect of the bacteria would not be apparent. Also it was to be anticipated that errors would be committed in the preparation and distribution of the inoculating material, and its protection from the sun. Such sources of error would be avoided in the repetition of the process, and the hope is justified that soil-inoculation for the cultivation of leguminous plants will gradually become an established custom in practical agriculture.”

VETCH, *Vicia villosa*.

1. Inoculated with pure cultivations of *Pisum sativum* nodule-bacteria.
2. Uninoculated.

rendered signal service in indicating how he may improve the quality and facilitate the distribution of his produce. Thanks to the exhaustive investigations on milk-bacteriology which have emanated from America and the Continent during the last few years, we have now no longer any justifiable excuse for ignoring the dangers which surround our dairy industries, and overlooking the responsibilities and grave consequences which attend the distribution of impure or contaminated milk.

Knowing as we do, that this rich fluid serves as a most suitable culture material for bacteria of all sorts and degrees, it is not surprising to learn that a few drops may contain a bacterial population of over a million, or as one investigator has expressed it, a single pint of milk may support from 33 to 56 millions of bacteria!

Under ordinary circumstances this vast army of microbes which may take possession of milk and cream is derived from sources other than the cow itself.

If we consider the insanitary conditions under which only too frequently milking is carried on,

the stifling atmosphere of the ill-ventilated milking-shed, rich in germ life, the carelessness as regards cleanliness not only in the condition of the animals themselves, but only too frequently in those entrusted with the milking of them, as well as the number of different hands the milk passes through before it reaches the consumer; if we take all these details into consideration, then indeed we shall cease to wonder that our milk in its raw condition can contain such multitudes of contaminating living centres.

Some idea of the manner in which bacteria flourish when once they gain access to milk may be obtained from the following observations.

A sample of milk was collected, and found to contain 153,000 microbes per cubic inch; after standing for an hour at a constant temperature of 59° Fahrenheit (15° Cent.), it contained 539,750 bacteria; at the end of seven hours this figure had risen to 1,020,000, whilst after the lapse of twenty-five hours as many as 85,000,000 were present per cubic inch!

That amidst this multitude of germs those associated with disease find their way into milk

has been shown repeatedly, and the responsibility of communicating scarlet fever, typhoid fever, diphtheria, and tuberculosis are only some of the heavy charges which have justifiably been brought up in connection with our milk supplies.

But it is not only that these germs may be a source of danger on hygienic grounds, but their presence is also productive of many of the difficulties with which dairy work is surrounded.

The milk of stall-fed cows or winter milk contains many more bacteria than are present in the milk of cows pastured in the field.

In milk derived from stall-fed cows, the *bacillus coli communis* is very frequently present, and this microbe, there can be no doubt, exerts a very prejudicial effect on milk, especially in the case of infants, in whom it is a frequent source of chronic diarrhoea.

But this is not all. This bacterium is also probably largely responsible for the trouble which is so familiar to the cheesemaker in the shape of "huffy" or "puffy" cheese.

This bacillus, which is capable of proliferating abundantly in milk, when it has once gained a

firm footing in this medium, prevents the proper development of the ordinary souring bacteria which are required for the ripening of cream and for the manufacture of cheese. We have said that the great mass of bacteria found in milk obtain access to this fluid subsequent to milking, but there is at least one great and highly important exception to this, and that is the *bacillus tuberculosis*, or tubercle bacillus, concerning which we have already heard so much.

Recent research has shown that tubercular disease is very prevalent amongst cattle, and that cows may be affected with tuberculosis in cases where the udder appears to be perfectly healthy, and that such animals are capable of infecting the milk derived from them with the germs of consumption.

This disease appears to be more prevalent amongst stall-fed cattle than those pastured in the open air; hence milk produced in towns is more likely to be infected with this dangerous micro-organism than that derived from the country.

Professor Bang of Copenhagen states that in some cow-houses, he has found as many as 80

per cent. of the cattle tuberculous, and there is not a doubt that the overcrowding of cattle in cow-houses may be as fertile a source of tuberculosis as is the case with the overcrowding of human beings.

Hirschberger again affirms that 10 per cent. of the cows living in the neighbourhood of towns where the conditions of their environment are not generally hygienically satisfactory, suffer from tuberculosis, and 50 per cent. of these animals yield milk containing tubercle bacilli. When we remember that these virulent germs can live for upwards of 120 days in butter, and over 35 in cheese, it is obvious what a source of danger their presence in milk must be.

Bacteriology, however, has fortunately not been content to simply indicate the dangers surrounding the consumption of dairy produce as ordinarily sent into the market, but it has patiently laboured to devise methods whereby not only may milk and its derivatives be rendered wholesome and germ-free, but also whereby those concerned in the commercial aspects of dairy produce may reap substantial benefit and reward.

The sterilization of milk has for some time past been extensively practised on the Continent, and the Swiss in particular have been very enlightened pioneers in this direction, whilst there is hardly a doubt that the successful manner in which the Danes have, as it were, "captured" the British butter-market, is largely due to the attention given to milk sterilization and the elaborate organization of their dairy industries.

The pasteurization of milk consists in maintaining the latter at a temperature of from 154° (68° Cent.) to 156° Fahrenheit (69° Cent.) generally by means of steam. To prevent its acquiring an unpalatable burnt flavour, it is kept by means of special apparatus in continual movement, whilst the temperature is so regulated that it never rises beyond 158° Fahrenheit (70° Cent.), at which point the change in taste which has brought boiled milk into such disrepute, takes place.

Pasteurization in the most approved apparatus for from 20 to 30 minutes kills, Dr. Bitter tells us, all the disease germs which are likely to be found in milk. Cream may also be pasteurized before being made into butter, and I recently had an

opportunity of making the acquaintance of butter which had been produced from sterilized cream subsequently inoculated with one particular bacterium upon which rested the whole responsibility of butter-conversion and flavour-production, and the result was extremely satisfactory.

More progress has, however, been made with cheese and the production of particular varieties from pasteurized milk by means of particular microbes, and there cannot be a doubt that as our knowledge advances we shall more and more be able to distinguish the friendly from the unfriendly varieties of dairy-bacteria, whilst we shall be able at will to produce what description of cheese we desire, and abandoning the uncertainty characterizing the rule of thumb methods which have too long prevailed, we shall resort to the practices based upon the latest scientific discoveries.

THE END.

THE ROMANCE OF SCIENCE.

A series of books which shows that science has for the masses as great interest as, and more edification than, the romances of the day.

Small Post 8vo, Cloth boards.

Coal, and what we get from it. By Professor RAPHAEL MELDOLA, F.R.S., F.I.C. With several Illustrations. 2s. 6d.

Colour Measurement and Mixture. By Captain W. DE W. ABNEY, C.B., R.E. With numerous Illustrations. 2s. 6d.

The Making of Flowers. By the Rev. Professor GEORGE HENSLOW, M.A., F.L.S. With several Illustrations. 2s. 6d.

The Birth and Growth of Worlds. A Lecture by Professor A. H. GREEN, M.A., F.R.S. 1s.

Soap-Bubbles, and the Forces which Mould Them.
A course of Lectures by C. V. BOYS, A.R.S.M., F.R.S. With numerous Diagrams. 2s. 6d.

Spinning Tops. By Professor J. PERRY, M.E., D.Sc., F.R.S. With numerous Diagrams. 2s. 6d.

Our Secret Friends and Foes. By P. F. FRANKLAND, F.R.S. With numerous Illustrations. New Edition, 3s.

Diseases of Plants. By Professor MARSHALL WARD, M.A., F.R.S., F.L.S. With numerous Illustrations. 2s. 6d.

The Machinery of the Universe. Mechanical conceptions of Physical Phenomena. By Professor A. E. DOLBEAR, A.B., A.M., M.E., Ph.D. 2s.

The Story of a Tinder-Box. By the late CHARLES MEYMOtt TIDY, M.B., M.S. With numerous Illustrations. 2s.

Time and Tide. A Romance of the Moon. By Sir ROBERT S. BALL, LL.D., Royal Astronomer of Ireland. With Illustrations. Fourth Edition, revised. 2s. 6d.

The Splash of a Drop. By Professor A. M. WORTHINGTON, F.R.S. With numerous Illustrations. 1s. 6d.

NATURAL HISTORY RAMBLES.

Fcap. 8vo., with numerous Woodcuts, Cloth boards, 2s. 6d. each.

IN SEARCH OF MINERALS.

By the late D. T. ANSTEAD, M.A., F.R.S.

LAKES AND RIVERS.

By C. O. GROOM NAPIER, F.G.S.

LANE AND FIELD.

By the late Rev. J. G. WOOD, M.A., Author of "Man and his Handiwork," &c.

MOUNTAIN AND MOOR.

By J. E. TAYLOR, F.L.S., F.G.S., Editor of "Science-Gossip."

PONDS AND DITCHES.

By M. C. COOKE, M.A., LL.D.

THE SEA-SHORE.

By Professor P. MARTIN DUNCAN, M.B. (London), F.R.S.

THE WOODLANDS.

By M. C. COOKE, M.A., LL.D., Author of "Freaks and Marvels of Plant Life," &c.

UNDERGROUND.

By J. E. TAYLOR, F.L.S., F.G.S.

HEROES OF SCIENCE.

Crown 8vo. Cloth boards, 4s. each.

ASTRONOMERS. By E. J. C. MORTON, B.A. With numerous diagrams.

BOTANISTS, ZOOLOGISTS, AND GEOLOGISTS. By Professor P. MARTIN DUNCAN, F.R.S., &c.

CHEMISTS. By M. M. PATTISON MUIR, Esq., F.R.S.E. With several diagrams.

MECHANICIANS. By T. C. LEWIS, M.A.

PHYSICISTS. By W. GARNETT, Esq., M.A.

MANUALS OF HEALTH.

Fcap. 8vo, 128 pp., Limp Cloth, price 1s. each.

HEALTH AND OCCUPATION. By the late Sir B. W. RICHARDSON, F.R.S., M.D.

HABITATION IN RELATION TO HEALTH (THE). By F. S. B. CHAUMONT, M.D., F.R.S.

NOTES ON THE VENTILATION AND WARMING OF HOUSES, CHURCHES, SCHOOLS, AND OTHER BUILDINGS. By the late ERNEST H. JACOB, M.A., M.D. (OXON.).

ON PERSONAL CARE OF HEALTH. By the late E. A. PARKES, M.D., F.R.S.

AIR, WATER, AND DISINFECTANTS. By C. H. AIKMAN, M.A., D.Sc., F.R.S.E.

MANUALS OF ELEMENTARY SCIENCE.

Foolscap 8vo, 128 pp. with Illustrations, Limp Cloth, 1s. each.

PHYSIOLOGY. By Professor A. MACALISTER, LL.D., M.D., F.R.S., F.S.A.

GEOLOGY. By the Rev. T. G. BONNEY, M.A., F.G.S.

ASTRONOMY. By W. H. CHRISTIE, M.A., F.R.S.

BOTANY. By the late Professor ROBERT BENTLEY.

ZOOLOGY. By ALFRED NEWTON, M.A., F.R.S., Professor of Zoology in the University of Cambridge. New Revised Edition.

MATTER AND MOTION. By the late J. CLERK MAXWELL, M.A., Trinity College, Cambridge.

SPECTROSCOPE (THE), AND ITS WORK. By the late RICHARD A. PROCTOR.

CRYSTALLOGRAPHY. By HENRY PALIN GURNEY, M.A., Clare College, Cambridge.

ELECTRICITY. By the late Prof. FLEEMING JENKIN.

MISCELLANEOUS PUBLICATIONS.

	s. d.
<i>Animal Creation (The).</i> A popular Introduction to Zoology. By the late THOMAS RYMER JONES, F.R.S. With 488 Woodcuts. Post 8vo.	<i>Cloth boards</i> 7 6
<i>Birds (Sketch Book of British).</i> By R. BOWDLER SHARPE, LL.D., F.L.S. With coloured Illustrations by A. F. and C. LYDON. Crown 4to.	<i>Cloth boards</i> 14 0
<i>British Birds in their Haunts.</i> By the late Rev. C. A. JOHNS, B.A., F.L.S. With 190 engravings by Wolf and Whymper. Post 8vo.	<i>Cloth boards</i> 6 0
<i>Evenings at the Microscope; or, Researches among the Minuter Organs and Forms of Animal Life.</i> By the late PHILIP H. GOSSE, F.R.S. A New Edition, revised by Professor F. JEFFREY BELL. With numerous Woodcuts. Post 8vo.	<i>Cloth boards</i> 5 0
<i>Fern Portfolio (The).</i> By FRANCIS G. HEATH, Author of "Where to find Ferns," &c. With 15 plates, elaborately drawn life-size, exquisitely coloured from Nature, and accompanied with descriptive text. Crown 8vo.	<i>Cloth boards</i> 8 0
<i>Fishes, Natural History of British: their Structure, Economic Uses, and Capture by Net and Rod.</i> By the late FRANK BUCKLAND. With numerous illustrations. Crown 8vo.	<i>Cloth boards</i> 5 0
<i>Flowers of the Field.</i> By the late Rev. C. A. JOHNS, B.A., F.L.S. New edition, with an Appendix on Grasses, by C. H. JOHNS, M.A. With numerous woodcuts. Post 8vo.	<i>Cloth boards</i> 5 0

	s. d.
<i>Forest Trees (The) of Great Britain.</i> By the late Rev. C. A. JOHNS, B.A., F.L.S. With 150 woodcuts. Post 8vo.....	<i>Cloth boards</i> 5 0
<i>Freaks and Marvels of Plant Life; or, Curiosities of Vegetation.</i> By M. C. COOKE, M.A., LL.D. With numerous illustrations. Post 8vo.....	<i>Cloth boards</i> 6 0
<i>Man and his Handiwork.</i> By the late Rev. J. G. WOOD, Author of "Lane and Field," &c. With about 500 illustrations. Large Post 8vo.	<i>Cloth boards</i> 7 6
<i>Natural History of the Bible (The).</i> By the Rev. CANON TRISTRAM, Author of "The Land of Israel," &c. With numerous illustrations. Crown 8vo.	<i>Cloth boards</i> 5 0
<i>Nature and her Servants; or, Sketches of the Animal Kingdom.</i> By the Rev. THEODORE WOOD. With numerous woodcuts. Large Post 8vo.	<i>Cloth boards</i> 4 0
<i>Ocean (The).</i> By the late PHILIP H. GOSSE, F.R.S., Author of "Evenings at the Microscope." With 51 illustrations and woodcuts. Post 8vo.....	<i>Cloth boards</i> 3 0
<i>Our Bird Allies.</i> By the Rev. THEODORE WOOD. With numerous illustrations. Fcap. 8vo....	<i>Cloth boards</i> 2 6
<i>Our Insect Allies.</i> By the Rev. THEODORE WOOD. With numerous illustrations. Fcap. 8vo.	<i>Cloth boards</i> 2 6
<i>Our Insect Enemies.</i> By the Rev. THEODORE WOOD. With numerous illustrations. Fcap. 8vo.	<i>Cloth boards</i> 2 6
<i>Our Island Continent.</i> A Naturalist's Holiday in Australia. By J. E. TAYLOR, F.L.S., F.G.S. With Map. Fcap. 8vo.	<i>Cloth boards</i> 2 6

	s. d.
<i>Our Native Songsters.</i> By ANNE PRATT, Author of “Wild Flowers.” With 72 coloured plates. 16mo.	
	<i>Cloth boards</i> 4 0
<i>Romance of Low Life amongst Plants.</i> Facts and Phenomena of Cryptogamic Vegetation. By M. C. COOKE, M.A., LL.D., A.L.S. With numerous wood- cuts. Large post 8vo.	<i>Cloth boards</i> 4 0
<i>Selborne (The Natural History of).</i> By the late Rev. GILBERT WHITE. With Frontispiece, Map, and 50 woodcuts. Post 8vo.....	<i>Cloth boards</i> 2 6
<i>Toilers in the Sea.</i> By M. C. COOKE, M.A., LL.D. Post 8vo. With numerous illustrations....	<i>Cloth boards</i> 5 0
<i>Vegetable Wasps and Plant Worms.</i> By M. C. COOKE, M.A. Illustrated. Post 8vo.....	<i>Cloth boards</i> 5 0
<i>Wayside Sketches.</i> By F. EDWARD HULME, F.L.S With numerous illustrations. Crown 8vo.	<i>Cloth boards</i> 4 0
<i>Where to find Ferns.</i> By FRANCIS G. HEATH, Author of “The Fern Portfolio,” &c. With numerous illustrations. Fcap. 8vo.	<i>Cloth boards</i> 1 6
<i>Wild Flowers.</i> By ANNE PRATT, Author of “Our Native Songsters,” &c. With 192 coloured plates. In two volumes. 16mo.....	<i>Cloth boards</i> 8 0
